For over sixty years we have employed a measure of inequality—the Lorenz curve—based on an unrealistic standard of equality. When used with annual income data, Lorenzian equality requires a flat age-income profile as well as equality of lifetime incomes. While the use of lifetime income data would negate the overspecification of equality built into the 45 degree line, empirical and theoretical considerations make this approach impractical. By developing a new equality reference function, suitable for use with annual income data, we not only avoid cumbersome data problems, but we open up to explicit examination the meaning of perfect equality. We also separate the issue of *intra*family variation in income over the life cycle (accounting for one-third of Lorenzian inequality) from the more basic issue of *inter*family differences in lifetime incomes. An application of the new concepts to *U.S.* income and wealth data reveals that estimates of inequality have been overstated by 50 percent, and the trend of inequality from 1947 to 1972 has declined by 23 percent. On equity as well as efficiency grounds there is a substantial case for rejecting the Lorenzian standard of absolute equality. The overstatement of inequality has lent false urgency to the demand for rectification of our income distribution.

APPENDIX

The traditional method of calculating the Gini concentration ratio involves a straight line approximation between plotted points of the Lorenz curve, and a simple formula for determining the resulting area (see James Morgan, Appendix). This, however, underestimates the area of inequality, especially if the number of data points drops below eight, a common occurrence since we frequently have income shares by quintiles. There seemed to be two obvious remedies but both were found wanting: fit an appropriate curve type by least squares; this however didn't pass through all the data points and was therefore rejected. The second approach involved fitting an $n-1$ degree polynomial which passed through every data point but showed unpredictable flips between the points. What is wanted is a smooth, continuous function which will pass through all the points, whether few or many, and be usable for interpolation between the points. A cubic-spline function described in Brice Carnahan et al., p. 63, fulfilled these conditions, and was used to derive L curves and P-reference curves for all the years required. A computer program was written to generate about 40 interpolated points between every two actual data points, and by integration provide the area of inequality and the Gini ratio.

As a test of the program, we had the benchmark Gini ratios for 1947–64 (Census, *Trends in the Income of Families . . .*) computed from disaggregated data. Using quintile shares plus the share of the top 5 percent for these 18 years, Gini ratios were computed by both the straight line and the cubic-spline methods, and compared with the Census coefficients. The straight line method produced underestimations averaging 3.5 percent. The cubic-spline method yielded correct estimates (to three significant figures) for one-third of the years, and for the entire sample produced an average error of only 0.6 percent (.002 Gini point). The smooth curves and the interpolations provided by the program also made possible meaningful comparisons of various points on the P and the L curves.

A Keynes-Friedman Money Demand Function

By Paul A. Meyer and John A. Neri*

Our main objective is to shed light on a question Milton Friedman regards as central: "Are transactions variables or asset variables most important in determining the demand for money?" (1970, p. 234). The recent theoretical literature on money emphasizes that money exists because it reduces transactions and information costs and saves time.[1] Recent empirical estimates of money demand have explored the influence of the real wage and unemployment rate, two variables which reflect the value of money in terms of reduced transactions time. While Dutton and Gramm's introduction of transactions variables like real wages is welcome, a more direct empirical answer to Friedman's question would give priority to the measurement of transactions and asset "constraints" rather than opportunity cost variables such as real wages.

In Section I we hypothesize that the demand for real balances depends on short-run expected income or transactions, which is not well measured by current income. The model distinguishes between short-run and long-run expected income and associates the former with transactions/finance variables and the latter with asset variables. Construction of the expectations variables incorporates elements from the *General Theory*, Keynes' (1937) replies to his critics, and Friedman's (1957, 1959) consumption and money demand studies. Reliance on doctrinal history alone leaves some ambiguities and our historical perspective may be questioned. Moreover, since John Muth has shown that permanent income may be the optimal predictor of income in any future period, we derive in Section II the expectations variables from the analysis of autoregressive processes. Using a stochastic model somewhat more general than Muth's, we show that Friedman's permanent income approximates the optimal forecast of long-run but not short-run income. The cumbersome mathematics necessary to derive optimal predictors shows that the optimal forecast for next period, a modified exponentially weighted average of past income, corresponds with our short-run expected income construct based on doctrinal history. In the regressions of Section III the variable discriminating between long-run expected income (asset motive) and short-run income (transactions motive) is highly significant in the M^1 (currency plus demand deposits) equations, supporting the transactions role of money. The model compares favorably with other estimates. Our conclusions are briefly summarized in Section IV.

I. Formulation of the Keynes-Friedman Money Demand Function

The generally accepted Keynesian money demand function relates money balances to current income which measures transactions requirements, and to an interest

[1] See Dean Dutton and William Gramm and the references they cite.

rate mainly because of the speculative motive. We feel Keynes would not object to, and indeed would even welcome, our modification of the transactions demand. Money demand is a function of the current expectation of income in the next period. Assuming constant elasticities so the relationship is linear in the logarithm,

$$M_t^* = \alpha_0 + \alpha_1 y_t^e + \alpha_2 r_t \tag{1}$$

where M^* is desired real balances, y_t^e is short-run expected real income, and r is an interest rate. To repeat, although not written explicitly the variables are *logs*. We temporarily abstract from an error term.

Some minor defense of (1) may be necessary. Assume there is approximately a one-to-one relationship between total transactions and income measures.[2] Considering the transactions motive alone, it is intuitively no less reasonable to relate desired real balances to planned transactions rather than current transactions. Equation (1) is entirely in accord with Keynes' thought if, as G. L. S. Shackle noted perceptively, we "... look in a part of the canon which few economists seem able to endure the sight of—or else they have never heard of it. It is his reply to his critics" (p. 516). In the debate with Ohlin, Robertson, and others over liquidity preference versus loanable funds, Keynes introduced a fourth motive for holding money—the finance motive. He states, "I should not have previously overlooked this point, since it is the copingstone of the liquidity theory of the rate of interest" (1937, p. 667). Stated succinctly, the finance motive refers to balances held for planned activity or what Keynes calls current *ex ante* output, in contrast to transactions balances held for actual activity or current *ex post* output. Of the two, Keynes states that the former may be the more important.

Speculating briefly on the reasons for the omission of the finance motive in the *General Theory*, Keynes was both overly pessimistic and optimistic about economists' ability to ascertain how income expectations are formed. Keynes distinguished between short-term and long-term expectations of output. With regard to the latter, Keynes position was "we simply do not know" (1936, pp. 147–64). On the other hand, short-run expected output or current *ex ante* output is well approximated by recent output, so well approximated that in the *General Theory* Keynes thought it was not necessary to distinguish between short-run expected output and actual current *ex post* output (1936, pp. 50–51). Thus Keynes' views on expected output differ markedly from his views on expected interest rates. Individuals do not uniformly expect interest rates in the near future to equal current rates, and the normal or permanent or long-run expected rate is bounded by past experience.

To express (1) in terms of observable magnitudes, we assume that individuals form income expectations in a manner analogous to the generally accepted view of Keynesian interest rate expectations, as interpreted by Franco Modigliani and Richard Sutch, for example. First, the Keynesian individual estimates normal or long-run expected income. We restrict Keynes somewhat by assuming normal income is virtually identical to the Friedman-Cagan formulation. That is, assume that the logarithm of normal real income y_t^n is an exponentially weighted arithmetic average of the logarithms of past income y.

$$\begin{aligned} y_t^n &= \sum_{i=0}^{\infty} (1-\beta)\beta^i y_{t-i} \qquad 0 < \beta < 1 \\ &= (1-\beta)y_t + \beta y_{t-1}^n \end{aligned} \tag{2}$$

---

[2] While bank debits may be more appropriate than income measures in the transactions approach, we show in a paper underway that debits and income are highly correlated. Moreover, debits have virtually no welfare implications, and construction of a price deflator for debits would be extremely difficult.

Equation (2) implies that the level of normal income is a geometric weighted average of past incomes, which is similar to Friedman's arithmetic average when the weights are the same. Indeed, Friedman and Anna Schwartz (1936b, p. 57) have suggested (2) as a way of measuring permanent income, and their suggestion was followed by Edgar Feige.[3] Corresponding to the treatment of interest rate expectations, deviations of current income from the normal are expected to be temporary. Expectations are regressive; income in the next period is expected to return towards the normal. Algebraically, next period or short-run expected income is given by

$$(3) \qquad y_t^e - y_t = \lambda(y_t^n - y_t)$$

where $0 \leq \lambda \leq 1$. The expected change in income depends simply on the deviation of current income from the normal. Thus, the Keynes-Friedman model states that past incomes influence current expectations only through their effect on normal income, which depends on the parameter β but not λ.

Substituting normal income in the expected income equation yields[4]

$$(4) \quad y_t^e = (1 - \lambda\beta)y_t + \lambda\beta(1 - \beta) \sum_{i=0}^{\infty} \beta^i y_{t-1-i}$$

With the aid of the recursion formula in (2), one can interpret expected income as (a) a weighted average of current and lagged normal income, where the weights are $(1-\lambda\beta)$ and $\lambda\beta$, respectively; (b) a weighted average of current and normal incomes at period t, where the weights are $(1-\lambda)$ and λ; or (c) current income plus a proportion λ of Friedman's temporary income. However interpreted, expected income is a modified exponentially weighted average of past income, the weights declining exponentially one period lagged. For any β, current (lagged) income has a greater (smaller) weight in expected than normal income if $\lambda < 1$. When $\lambda = 1$, full adjustment back to normal is expected to occur next period.[5]

Returning to the original money demand function, we make two alternative assumptions about the relationship between desired and actual balances.

$$(5a) \qquad M_t^* = M_t$$

$$(5b) \qquad M_t - M_{t-1} = \gamma(M_t^* - M_{t-1})$$

The first equation in (5) makes the restrictive assumption that actual and desired balances are equal, while the second equation states that during a period t only a fraction, $0 < \gamma < 1$, of the percentage difference between desired and initial balances is made up. Of course, if the adjustment coefficient γ equals unity, (5b) is reduced to (5a). The theoretical foundation of (5b) in the context of demands for liquid assets is unclear. Stephen Goldfeld discusses other partial adjustment mechanisms but their theoretical underpinnings are in our minds hardly more satisfactory. In any case, by assuming (5b) we can compare a limited number of regressions with numerous studies, being sure that any difference in results arise from other features of the model.

Consider the simpler instantaneous adjustment case first. Substituting (5a) and (4) in (1) gives

$$(6) \quad M_t = \alpha_0 + \alpha_1(1 - \lambda\beta)y_t + \alpha_1\lambda\beta(1 - \beta) \sum_{i=0}^{\infty} \beta^i y_{t-1-i} + \alpha_2 r_t$$

---

[3] The slight modification of Friedman's measure facilitates computations since we assume money demand is linear in the logarithms (constant elasticity). Friedman's weights sum to slightly more than one to allow for growth; we could allow for growth by introducing a constant in (2), but this would not change the form of the regressions or their interpretation.

[4] Henceforth, expected income without modification will always refer to short-run expected income. Normal or permanent refers to long-run expected.

[5] Given consistent realization of income expectations, i.e., $y_t^e = y_{t+1}$, it can be shown that actual and normal income converge.

Since all variables are expressed in logarithm, α_1 and α_2 are elasticities. Previous empirical studies suggest that α_1, the elasticity of real balances with respect to income should be about unity, and α_2, the interest rate elasticity, should be between zero and one. The elasticity should be greater for long rates than short rates but within the stated limits in either case. Equation (6) cannot be estimated as it stands. Since the regression coefficients beginning in $t-1$ are restricted to fall exponentially, apply a Koyck transformation. Lagging (6), multiplying both sides by β, and subtracting gives a reduced equation which, given the empirical work that follows, is most conveniently written as

$$\text{(7a)} \quad M_t - \beta M_{t-1} = C_0 + C_1 y_t + C_2 y_{t-1} + C_3[r_t - \beta r_{t-1}]$$

where

$$C_0 = (1-\beta)\alpha_0$$
$$C_1 = \alpha_1(1-\lambda\beta)$$
$$C_2 = \alpha_1\beta(\lambda-1)$$
$$C_3 = \alpha_2$$

The behavioral parameters in terms of β and the coefficients of the reduced equation are

$$\text{(8)} \quad \lambda = (C_1\beta + C_2)/\beta(C_1 + C_2)$$
$$\alpha_1 = (C_1 + C_2)/1 - \beta$$
$$\alpha_2 = C_3$$

Examination of (7a) and (8) shows that if lagged balances and current and lagged interest rates were included as independent variables, the structural parameters α_2 and β would be overidentified. In the empirical work we estimate (7a) by iterating over β.[6] Use of the Koyck transformation produces another problem in addition to overidentification, namely the introduction of lagged balances. This problem is not avoided by a simple transformation that includes lagged balances on the left-hand side of (7a). We take this problem up again in the empirical Section III.

If only partial adjustment occurs during the period, then using (5b) instead of (5a) and following procedures similar to those which yielded (7a) gives

$$\text{(7b)} \quad M_t - \beta M_{t-1} = C_0' + C_1'(M_{t-1} - \beta M_{t-2}) + C_2' y_t + C_3' y_{t-1} + C_4'(r_t - \beta r_{t-1})$$

Equation (7b) is another form of the equations to be estimated. Again if M_t were the dependent variable and M_{t-1} and M_{t-2} as well as r_t and r_{t-1} were included as separate independent variables, the structural parameters would be overidentified. To save space we simply assert that as was true for (7a), the C_i' coefficients in (7b) are functions of the behavioral parameters and can be unscrambled to determine the behavioral coefficients, given β.

Goldfeld and David Laidler (1969) state that the transactions approach focuses on income, and presumably expected income, as the scale variable; the asset approach uses long-run variables such as permanent income or wealth. Given this view, our model indicates that λ is the crucial parameter in the transactions-asset motive controversy. Recall that if $\lambda = 0$, expected income reduces to current income, and the transactions/finance approach is supported. It is unlikely that $\lambda=0$ since Laidler (1966a) showed that a distributed lag of income is superior to current income. The asset approach to money demand presumably is valid if $\lambda=1$ as expected income then equals permanent income as computed by Friedman. If λ is significantly different from unity (but not necessarily equal to zero), then according to our model money demand depends on expected income or transactions and not on permanent income or assets. Of course, λ may be significantly different from unity and the asset motive may still predominate simply because the Friedman method of computing permanent income contained in the model is incorrect, the correct method of computing permanent income being our modified exponentially weighted average. If we relied exclusively on doctrinal history, the equation discriminates between asset and transactions only given the Keynes-Friedman assumption. This lack of definiteness is largely eliminated by considering optimal prediction criteria in a stochastic model and by the relationship between coefficient estimates and the definition of money in the empirical tests.

---

[6] It may appear that our estimation technique is arbitrary; we could have searched over α_2. However, given the objective of minimizing the squared residuals, which as we argue later is the correct objective, it can be shown that the direction of search is irrelevant, assuming perfect searches. In other words, searching for values of α_2 and estimating λ, β, and α_1 would yield the same parameters as those shown in Table 1. We searched over β simply because the theory suggested a range of values for this parameter. While we also could have scanned over β, computed permanent income, and estimated equation (6) directly, this alternative is less desirable on several counts. We would have to use estimates of *NNP* for earlier periods (pre-1897), and our impression is that the estimates are less reliable the further one goes back in time. As β approaches unity, data sufficient to compute permanent income are not available. War year data are completely excluded in (7a) and (7b) but are necessary in (6) to compute normal income.

II. Autoregressive Processes and Optimal Predictors

Suppose that the myriad of factors influencing income are such that its time-series can be regarded as generated by independent "shocks" a_t. As a specific example, let income be a linear function of independently and normally distributed random variables with mean zero and common variance where the coefficients or weights of the lagged variables are equal,

$$y_t = a_t + k_0 \sum_{i=1}^{\infty} a_{t-i} \tag{9}$$

where $0<k_0<1$

To repeat, the a's are independent, but looking at (9) shows that output y_t will be serially correlated. Muth has analyzed this stochastic model, showing that permanent income as computed by Friedman is the optimal (in the sense of minimizing the mean square error of prediction) predictor of income in any future time period, given simply the observed past incomes. A more general stochastic model than Muth's is

$$y_t = a_t + \sum_{i=1}^{\infty} (k_0 + (1-k_0)k_1^i)a_{t-i} \tag{10}$$

where k_0 and k_1 lie between zero and one. Throughout most of this section, we assume the parameters are known. Our model reduces to Muth's when $k_1=0$ so that the weights of past disturbances are all equal to k_0. As Muth notes, equation (9) implies that the shocks contain two distinct effects, permanent and temporary. In the current time period the shock has a temporary effect $(1-k_0)$ plus a permanent effect k_0, so that current shocks have a weight of unity. The temporary effect is zero in all subsequent time periods. According to (10) the shock has a "lingering" and permanent effect, given $k_1\neq 0$. The weight of a shock is unity in the current period and in subsequent periods approaches k_0, its permanent effect. It certainly is reasonable, but contrary to the Friedman-Muth model, to assume that a shock in, say, 1973 has a greater effect on output in 1975 than 1985. An observation generated by (10) may also be expressed as an infinite weighted sum of past observations plus a random variable. Repeatedly lagging (10) and substituting yields

$$y_t = w_1' y_{t-1} + \sum_{i=0}^{\infty} w_{1+i} y_{t-1-i} + a_t \tag{11}$$

where
$$w_1' = k_1/(1-k_0(1-k_1))$$
$$w_{1+i} = k_0(1-k_0)(1-k_1)^2 \cdot (1-k_0(1-k_1))^{i-1}$$

Now suppose that at period t we are to

forecast y_{t+s} which is to be a linear function of y_t and previous observations. Since we are interested in forecasts with different lead times, denote the optimal forecast at t for $s \geq 1$ periods forward by $y_t^e(s)$. In terms of the notation of the previous section $y_t^e = y_t^e(1)$. How does one weight the observations in order to minimize the mean square error of prediction? Let the optimal forecast be

$$\text{(12)} \qquad y_t^e(s) = v_1(s)y_t + v_2(s)y_{t-1} + v_3(s)y_{t-2} + \dots$$

where the weights $v_1(s)$, $v_2(s)$, . . . , to be determined are generally functions of the lead time s of the forecast. Clearly from (11) actual income in period t+s is

$$\text{(13)} \quad y_{t+s} = w_1' y_{t+s-1} + \sum_{i=0}^{\infty} w_{1+i} y_{t+s-1-i} + a_{t+s}$$

The mean square error of prediction at period t is $E[y_{t+s} - y_t^e(s)]^2$. It is well known that the variance is less than the second moment about any number other than the mean. Consequently, since the prediction error is minimized given the realized shocks through period t, the optimal predictor is the conditional expectation.[7]

$$\text{(14)} \qquad y_t^e(s) = E[y_{t+s} \mid y_t, y_{t-1}, \dots] = E[y_{t+s} \mid t]$$

Examination of (10) and (11) shows that y is not time stationary. Let $s=1$ and take the (conditional) expectation of (13)

$$\text{(15)} \qquad E[y_{t+1} \mid t] = w_1' y_t + \sum_{i=0}^{\infty} w_{1+i} y_{t-i}$$

Equating coefficients in (12) and (15) gives

$$\text{(16)} \qquad \begin{aligned} v_1(1) &= w_1' + w_1 \\ v_i(1) &= w_i \qquad i = 2, 3, \dots \end{aligned}$$

For $s=2$ and making use of (15), the conditional expectation of (13) is

$$\text{(17)} \quad \begin{aligned} &E[y_{t+2} \mid t] \\ &= (w_1' + w_1)E[y_{t+1} \mid t] + \sum_{i=1}^{\infty} w_{1+i} y_{t+1-i} \\ &= [(w_1' + w_1)^2 + w_2]y_t + \sum_{i=1}^{\infty} [(w_1' + w_1)w_{1+i} + w_{2+i}]y_{t-i} \end{aligned}$$

Again equating coefficients gives

$$\text{(18)} \quad \begin{aligned} v_1(2) &= (w_1' + w_1)^2 + w_2 \\ &= [v_1(1)]^2 + w_2 \\ v_i(2) &= (w_1' + w_1)w_i + w_{1+i} \\ &= v_1(1)w_i + w_{1+i} \qquad i = 2, 3, \dots \end{aligned}$$

Proceeding in this manner it can be shown that in terms of the original parameters k_0 and k_1,[8]

$$\text{(12}'\text{)} \qquad y_t^e(s) = [1 - \theta(s)]y_t + \theta(s)y_t^n$$

where

$$\theta(s) = \frac{(1 - k_0)(1 - k_1^s)}{1 - k_0(1 - k_1)}$$

$$y_t^n = k_0(1 - k_1) \sum_{i=0}^{\infty} (1 - k_0(1 - k_1))^i y_{t-i}$$

The optimal forecast is a modified exponentially weighted average, that is, a weighted average of the current and normal values at period t. The weights vary according to the lead time of prediction in our model with lingering and permanent shocks. As we expected if $k_1=0$, then

---

[7] For a rigorous proof, see G. E. P. Box and J. M. Jenkins, p. 128.

[8] While there are some advantages in letting the coefficient of y_{t-1} in (15) be $w_1' + w_1$, at this point a transformation is useful. Let $Z_1 = w_1' + w_1$ and $Z_i = w_i$; $i = 2, 3, \dots$. Box and Jenkins, p. 142, showed that

$$v_i(s) = Z_{i+s-1} + \sum_{h=1}^{s-1} Z_h v_i(s - h)$$

Using this equation and the well-known recursion formula for permanent income, (12′) follows more readily.

$\theta(s)=1$ and normal income is the optimal forecast for all periods. Contrary to the Muth-Friedman model given by (9), our optimal predictor with $k_1 \neq 0$ depends on the time interval of the forecast.

Equation (12′) yields optimal forecasts of income given that the forecasts are a linear function of y_t and previous observations alone. Could the forecasts be improved by incorporating further information and behavioral and accounting relationships? The answer is not clearly yes. For example, Charles Nelson showed that beyond the sample period over which the FRB-MIT-PENN model was fitted the mean square error was more than twice as large as the errors in predicting income with a single autoregressive equation, presumably because of the specification and sampling errors in large scale models. Treating income "as if" it were generated by an autoregressive process and estimating its parameters certainly facilitates forecasting; whatever other data besides lagged income one has available may be superfluous or even dangerous.

It is desirable to reconsider forecasting one period ahead and in the distant future. For s=1, equation (12′) becomes after some rearranging

$$(19)\quad y_t^e(1) = [1-(1-k_0)(1-k_1)]y_t + [(1-k_0)(1-k_1)]y_{t-1}^n$$

The doctrinal forecast of income given by (4) and the optimal forecast derived from the time-series model (19) have the same form where

$$(20)\quad \lambda = (1-k_0)(1-k_1)/1-k_0(1-k_1)$$
$$\beta = 1-k_0(1-k_1)$$

Is Friedman's normal or permanent measure an optimal forecast in a model where optimal forecasts for all periods are not identical? No direct and definitive answer to this question is possible since Friedman purposely left vague the theoretical concept of permanent income. An indirect approach suggests itself. Calculate expected income for alternative lead times and see if some expected income approaches Friedman's empirical construct. Given our restrictions on the values of k_0 and k_1, examination of (12′) shows that θ is strictly positive. Differentiating with respect to the lead time

$$(21)\quad \partial\theta/\partial s = \frac{-(1-k_0)k_1^s \log k_1}{1-k_0(1-k_1)} > 0$$

The weight on normal income is positively related to the lead time of the forecast. Expressed in terms of λ and β, which are estimated in the following section, equations (12′) and (20) show that as the lead time becomes large the forecast approaches

$$(22)\quad y_t^e(\infty) = \left[\frac{(1-\lambda)(1-\beta)}{1-\beta(1-\lambda)}\right]y_t + \left[\frac{\lambda}{1-\beta(1-\lambda)}\right]y_t^n$$

Anticipating the empirical results, using the narrow definition of money (currency plus demand deposits), the minimum and maximum estimated values of $\lambda/[1-\beta(1-\lambda)]$, are .91 and .96, respectively, in regressions using alternative interest rates and making alternative assumptions about the adjustment of desired to actual money balance. For $y_t^e(1)$ the weight of y_t^n is λ, which varies between .56 and .77. Thus our empirical results indicate the optimal forecast of income in the distant future is approximately given by Friedman's normal income measure.

$$(23)\quad y_t^e(\infty) \cong y_t^n$$

While other interpretations are possible, equating permanent income with a long-run forecast is a reasonable interpretation of Friedman and assures optimality for his income measure.

III. Estimates of the Model

In this section we present regression estimates of the model developed in Section I using annual data covering the period 1897–1960 with the war years 1917–19 and 1941–45 excluded. The data which are expressed in *logs* include: (a) National Bureau of Economic Research (*NBER*) unpublished figures on *NNP*, the four-six month prime commercial paper rate, and an implicit price index (1929 base); (b) M^1, currency and demand deposits, and the yield on twenty-year corporate bonds provided by Gregory Chow up to 1958 and the Federal Reserve *Bulletin* and *Statistical Abstract* for 1959–60; and (c) M^2, currency plus demand deposits plus time deposits, taken from Friedman and Schwartz (1963a). The data and time periods were chosen for a basis of comparison with other empirical studies on the demand for money such as Chow (1966, 1968), Friedman (1959), Laidler (1966a,b), and Allan Meltzer. The use of annual data in no way implies that money balances finance outlays one year hence.

Although we emphasize the role of money as a medium of exchange, we do not simply drag M^2 along to multiply the number of regressions. Our model implies that the values of some parameters depend crucially on the definition of money. For example, λ, a parameter discriminating between asset and transactions motives, should be closer to unity when money is defined as M^2 as opposed to M^1. Desired medium of exchange balances depend on planned short-term transactions, which gives a value of λ different from unity. The broader definition of money includes an asset which is not a medium of exchange. For such an asset, λ should be approximately unity since total assets or permanent income is a better determinant than planned transactions, as Keynes noted (1930, p. 36). Since time deposits were approximately 40 percent of M^2, in the M^2 regressions λ may not be significantly different from unity. The appropriate income constraint depends on the empirical definition of money.

To our best knowledge, studies that include permanent income or nonhuman wealth and ignore the transactions (finance) motive find that M^1 is systematically more sensitive to market interest rates than M^2. That is, for both short- and long-term interest rates, the absolute elasticity is substantially greater for the narrower definition of money. Only H. R. Heller finds that the interest rate elasticity is greater for M^2, and his preferred constraint variable is nominal income. From the theory of omitted variables, the systematic relationship between estimated interest rate elasticities and the definition of money is as it should be when the transactions motive is ignored. The asset, general theory of choice approach is silent about the relative interest rate elasticities of different assets. The percentage shifts from currency and demand deposits to all other assets including time deposits in response to higher relative interest rates is as a first approximation, according to this view, equal to the percentage shift from time deposits to other assets. As market interest rates rise, the time deposit rate generally fails to increase proportionally so that the relative time rate falls. Moreover, the relative rate on M^1 falls even more because currency bears no interest and interest payments on demand deposits have been prohibited since the 1930's. Services which increase the return on demand deposits cannot be expanded rapidly. Lack of a good series on deposit rates forces their omission. Consequently, for a given increase in market rates, there will be a greater shift from demand than time deposits to all other assets, and some demand deposits shift to time deposits as the relative time/demand deposit rate rises. The estimated market interest rate elasticity should be greater for the narrower definition of money given the crucial assumption that the elasticity with respect to interest rates in general is the same for both assets. In other words, if the "true" elasticities of M^1 and M^2 with respect to market rates are equal, the omission of deposit rates will bias downward (towards zero) less the estimated elasticity of M^1.

There should be no systematic relationship between the estimated market rate elasticities and the definition of money if the transactions motive significantly explains M^1. Transactions balances are highly interest inelastic according to classical and Keynesian views, or at least more inelastic than other assets like time deposits. The omission of deposit rates biases towards zero the coefficient of market rates less for M^1 than M^2, but the true coefficient is absolutely smaller in the M^1 regressions. Therefore, the estimated market rate elasticities may even be smaller for M^1. It is the pattern of interest rate coefficients which sheds light on the problem previously posed: do the distributed lag (4) and our reduced equations (7a) and (7b) really contain a transactions element or are they simply providing better measures of an asset constraint?

The ordinary least squares (*OLS*) estimates of (7a) and (7b) are presented in Table 1. Since the coefficients of the reduced equations are of little interest, we only present the structural parameters. The standard errors of the estimated structural parameters, which are nonlinear functions of the reduced parameters, were obtained using a formula presented by Lawrence Klein. The table shows the standard errors in parentheses. β is the parameter used to compute permanent income had we not applied a Koyck transformation to get (7a) from (6). In estimating (7a) and (7b) we scanned over β at 0.05 intervals between zero and one and chose that value of β which minimizes the standard error of the estimate. Since the dependent variable clearly depends on the value of β, minimizing the unexplained

TABLE 1—ESTIMATES OF MONEY DEMAND FUNCTIONS
Equations (7a) and (7b)

Dependent Variable	β	Transactions/ Assets λ	Income Elasticity α_1	Interest Rate Elasticity		Stock Adjustment Coefficient γ	$\frac{\lambda}{1-\beta(1-\lambda)}$	Unbiased Squared Standard Error of the Estimate
				α_2^S	α_2^L

		(.068)	(.077)		(.067)	(.057)		(1.63)

sum of squares is preferable to maximizing the *relative* explained sum of squares, R^2. The number in parentheses in the last column is the mean of the dependent variable.

We generally limit discussion of the table to the first four regressions, which assume instantaneous adjustment. Looking at the latter stock-adjustment regressions we see that γ is virtually equal to unity, indicating rapid adjustment of actual to desired balances. Moreover, the value of no other parameter is sensitive to the adjustment assumption made. The estimates of γ are extremely encouraging. If the most liquid asset money, however defined, is not virtually completely adjusted to its desired level within a year, how long are other lags? While Feige also found complete adjustment within a year, Chow (1966) and Martin Bronfenbrenner and Thomas Mayer have found quite long lags.

The income elasticities are in accord with the study by Meltzer. They are close to unity, the only significant difference being the regression of M^2 on the short-term interest rate. The income elasticity of M^2 is uniformly about 0.15 greater than the elasticity of M^1 in corresponding equations. Like Laidler (1969a), we find no support for Friedman's (1959) view that money is a luxury.

The values of λ are entirely consistent with our hypothesis. Given the doctrinal and time-series justifications for considering the modified exponentially weighted average as expected income, and equating approaches to money demand with the time horizon implied by the best scale variable, finance requirements and not assets explain money demand particularly when money is defined as M^1. A value of λ significantly different from unity in the M^1 regressions indicates that short-period expected income is the determinant of the medium of exchange, and short-period expected income is different from Friedman's permanent income. When one broadens the definition of money to include time deposits, permanent income plays a more important role. The value of λ rises in the M^2 regressions and while still less than unity, the differences are of only marginal significance at the 5 percent level in the regressions with the short-term interest rate. Expected income does not equal current income; λ is significantly different from zero. Planned expenditures or the finance motive rather than current expenditures determine money demand. The tendency to equate the superior performance of permanent over current income in long-run or instantaneous adjustment regressions like (1)–(4) with superiority of the asset motive is incorrect. The (planned) transactions motive is significant, but to capture it (7a) shows that one must include more in the regression than current income and current interest rates.

The interest rate elasticities are relatively low but significant, at least at the 5 percent level. From a purely technical viewpoint, the lower elasticities for the short rate may simply reflect the larger swings of short rates over long rates. As we expected there is no systematic relationship between interest elasticities and the definition of money. M^1 rather than M^2 is less responsive to movements in the short-term rate while the reverse holds for the long rate.

The next to last column in Table 1 shows the weights of permanent income in distant forecasts in an optimal forecasting model. Ordinary least squares (*OLS*) estimates of (7a) are acceptable. If the disturbance terms follow the classical least squares properties, J. Johnston shows that with a lagged dependent variable *OLS* estimators are biased, but the bias in our case is quite small since the sample size is more than fifty. Moreover, the *OLS* estimators are maximum-likelihood, consistent, and asymptotically efficient. If the disturbance term is autocorrelated, however, *OLS* is no longer even consistent and another estimation technique would be necessary. The Durbin-Watson statistic is biased towards indicating random disturbances in the presence of the lagged dependent variable on either left- or right-hand side of the equation. Therefore, to test for autocorrelation according to Johnston (p. 313) we estimate (7a) by *OLS* with lagged balances on the right-hand side and computed Durbin's *h*-statistic. Using both definitions of money and both interest rates, in no case could we reject at the 5 percent level the null hypothesis that the disturbance terms were uncorrelated. Consequently, nothing more complicated than the *OLS* estimators in Table 1 are necessary.[9]

How does our money demand function compare with other estimates? Having already shown that our coefficients are "reasonable," all that remains is a comparison of the fit. Since equations may be subject to substantial sample bias, we feel evaluating predictive power beyond the period used to estimate the regression is far superior to comparing R^2 or errors in the sample period. Evaluating the predictive ability of our equations against all others using alternative combinations of interest rates and money definitions would, of course, be impossible. Money demand regressions are typically log-linear, and the narrow definition of real balances and the long-term rate of interest are more commonly used. To test various hypotheses, Chow (1966, 1968) and Laidler (1966a,b) estimated a battery of regressions using as independent variables current and lagged values of actual income, Friedman's permanent and temporary income, wealth, interest rates, and lagged balances. Both Chow and Laidler find that permanent income as computed by Friedman is the appropriate constraint for a long-run money demand function, and Chow further includes current income and lagged balances in his short-run function to capture a modified stock-adjustment mechanism. Therefore, we compare the errors in predicting the *log* of real balances with our (7a), the parameters given by the third line of Table 1, against the permanent income variant of equation (7a), (assumes $\lambda = 1$), and the following equations:[10]

$$M_t^1 = -0.989 - 0.721 r_t^L - 0.145 N_t + 1.145 y_t^P$$

Laidler (1966b, p. 522)

$$M_t^1 = 0.281 - 0.298 r_t^L + 0.216 y_t^P + 0.162 y_t + 0.607 M_{t-1}^1$$

Chow (1968, p. 1242)

where N is population, y_t^P is Friedman's permanent measure, and the other variables are as previously defined.

Referring to Table 2, the dates under the authors' names are the estimation period. Prediction errors for five years beyond the estimation period and for 1961–63 are calculated. The first line shows the errors using our (7a), while the second line shows the errors for the permanent income variant of (7a). That is, we

---

[9] If one assumed that (1) contained a normally and independently distributed error term, then the disturbance in (7a) would be serially correlated. In this case the standard errors presented in Table 1 are biased and the estimation technique suggested by J. Phillip Cooper would be appropriate. One is never on firm ground in specifying disturbance terms, and the assumption of the first sentence is no more reasonable than the null hypothesis in the text.

[10] We ignore Meltzer's important study which emphasizes nonhuman wealth because the exchange between Chow and Karl Brunner and Meltzer showed that "... some very slight differences in the measure of wealth that was used" (p. 1237) can alter coefficients dramatically. The aggregate equivalent of Laidler's equation which is in per capita terms is given. That is, Laidler's equation is $M^1/N = -0.989 - 0.721\, r_t^L + 1.145\, (y_t^P/N)$, using our notation where M^1 is *log* real balances, and similarly for other variables.

TABLE 2—PREDICTION ERRORS

		Prediction Errors for *Log* (Narrow) Real Balances			
Study	Independent Variables	Period	Mean Error	Mean Absolute Error	Standard Deviation of Errors
Meyer-Neri (1897–1960)	y_t, y_{t-1}, M_{t-1}, r_t, r_{t-1} (constrained)	1961–65	−.009	.014	.019
		1961–63	.001	.015	.016
Meyer-Neri (1897–1960)	y_t, M_{t-1}, r_t r_{t-1} (constrained)	1961–65	−.006	.023	.029
		1961–63	−.020	.030	.031
Laidler (1919–60)	y_t^P, r_t, N	1961–65	.030	.030	.028
		1961–63	.031	.031	.016
Chow (1897–1958)	y_t^P, y_t, r_t, M_{t-1}	1959–63	.053	.053	.020
		1961–63	.041	.041	.014
		1959–61	.058	.058	.015

assumed $\lambda=1$, deleted y_{t-1} as an independent variable, and then iterated over β at 0.05 intervals so that the ratio of the coefficient of r_t and r_{t-1} is constrained to be minus β. The value of β minimizing the squared standard error of the regression was chosen. With regard to the transactions/finance and wealth controversy, the first two lines are most relevant since the same period and estimation method was used. Our (7a) does appreciably better than the permanent income variant however the prediction error is measured. The mean error in predicting *log* money balances is virtually equivalent to the relative error in predicting the level of money balances.[11] The basic hypothesis underlying lines 2 and 3—money demand depends on permanent income and the long rate—is identical, the difference being the sample period and estimation technique.[12] Computing permanent income directly rather than applying a Koyck transformation yields systematic underestimation of real balances, the mean and mean absolute errors are equal, but has little effect on the standard deviation of the errors for the full 1961–65 period. Chow's short-run equation also consistently underestimates money balances. In terms of the standard deviation of the prediction errors, there is little difference between our (7a) and Chow's equation.[13] If we had chosen to compare root mean square errors, the results would be more favorable for our hypothesis since our mean prediction error is small.[14] The greater variability of the errors for 1958–63 relative to the subperiods might be explained by the autocorrelation of Chow's regression (Durbin's h-statistic is significant at the 1 percent level). Table 2 does not demonstrate beyond doubt the superiority of the transactions/finance approach; it does show that this approach does at least as well as the wealth approach. Moreover, we find our estimates of complete adjustment of actual to desired balanced within a year more plausible than Chow's long lags.

---

[11] $Log M - log \hat{M} = -log \quad (\hat{M}/M) \cong -((\hat{M}/M)-1) = (M-\hat{M})/M$, since $\hat{M}/M$ is close to unity.

[12] We searched to find the optimal income weights in the money demand function while Friedman's permanent income has weights which maximize the correlation between income and consumption. Even if the income weights allowing for growth and the sample period of the dependent variable were identical, applying a Koyck transformation instead of computing normal income directly could lead to different estimates because a longer income series is necessary to compute normal income directly and the unobserved errors of the regressions would not be identical.

[13] Some caution is necessary in comparing Chow's prediction errors against the others because a slightly different variable is being predicted. Chow deflates nominal balances by the personal consumption expenditures price index while Laidler and the authors deflate by the *NBER* implicit price index for *NNP*, variant III.

[14] The mean square error, which probably is the most important property of an estimator, can be computed from Table 2 by noting that it equals the variance of the estimator plus the square of the mean error (bias).

IV. Summary

The appropriate definition of money is the subject of substantial controversy. Nevertheless, everyone is willing to include currency and demand deposits. Particularly if money is defined to include only these two assets, it is inconceivable in our minds that recognizing that money is a medium of exchange will add nothing to the empirical estimates of money demand. If at this point we may engage in some armchair empiricism and philosophizing, the quest for generality in economics has gone too far. Laidler (1969) wonders why anyone would consider motives for money when motives for refrigerators are ignored. Let us admit it, refrigerators do keep beer and watermelon cold, and this may improve estimates of the demand for refrigerators. A less than exhaustive but more than cursory examination of our newspapers shows that small refrigerators (less than 5 cubic feet) are much more heavily advertised (and sold) in the spring and summer than in the winter. Money is the medium of exchange; this bit of information should add something. It does. In simple regressions of money on an interest rate and either current or permanent income, the latter has greater significance. This has led to the incorrect conclusion that the asset approach dominates. The amount of real balances demanded depends on real planned transactions, which are not well measured by either current or permanent income alone. The Keynes-Friedman approach leads to money demand being a function of a modified exponentially weighted average of income, which measures finance requirements.

The pattern of interest rate coefficients further supports the transactions/finance approach. While this approach is contrary to Friedman's views, we find no support for a Keynesian liquidity trap. We ran several tests for a liquidity trap and like Laidler (1966b) could find none. Although statistically significant, the interest rate elasticity of money is very low, about one-half other estimates. The empirical results described in this paper suggest the desirability of further work along the lines of the recent theoretical literature emphasizing that money reduces transactions and information costs and saves time.

Short-Run Asset Effects on Household Saving and Consumption: The Cross-Section Evidence

By IRWIN FRIEND AND CHARLES LIEBERMAN*

This paper introduces a new approach to the measurement of the short-run effects of capital gains on household saving and consumption. Previously, the timing and magnitude of these asset effects have been estimated exclusively from time-series data—either from a single equation consumption function or, more commonly in recent years, from a large-scale econometric model. The basic difficulty with the approach based on aggregate time-series data is the small number of independent observations available for determining the appropriate parameters, especially in a model with a large number of structural equations and a large number of alternative forms for each equation.

The economic importance of obtaining further insights into the short-run impact of capital gains on saving is highlighted by the MIT-PENN-SSRC (*MPS*) model, which asserts that one of the most important channels of transmission of monetary policy is the wealth effect on consumption.[1] The updated (January 1973) version of the *MPS* model implies that a \$1.00 capital gain increases the long-run rate of consumption by \$.054, with most of this effect taking place in the first year. However, while the estimated long-run effect has changed only moderately in different recent versions of the model, the timing of that effect has changed greatly. Moreover, as discussed subsequently, other time-series analyses have provided radically different results for the magnitude and timing of asset effects on consumption.

Given the large margin of indeterminacy in estimating the pattern of asset effects on consumption from time-series data, it is surprising that survey data have not been used as a check on the time-series analysis. This is not to say that survey data do not have deficiencies of their own, but simply that the paucity of independent observations characterizing time-series, compounded by temporal changes in the economic structure, cannot be remedied without the use of cross-section information. The most serious deficiencies in survey or cross-section data can be corrected with the availability of sufficient resources. Panel data covering the same households (or groups of households) over several consecutive periods of time are necessary to avoid some of the limitations of a single cross-section, but highly useful information on short-run asset effects can be obtained from appropriate information collected in a single cross-section.

The cross-section data used for this paper consist of information on saving, income, and assets from two surveys of 2,159 households in 1963 (with income

* Professor of finance and economics, University of Pennsylvania, and assistant professor of economics, University of Maryland, respectively. We wish to thank the National Science Foundation for financial support and the Board of Governors of the Federal Reserve System for making previously unpublished survey data available to us.

[1] The latest published version of the *MPS* model appears in Franco Modigliani, but a more recent version is available in *MIT-PENN-SSRC Econometric Model of the United States*, January 1973.

data for 1962 as well as 1963) conducted by the Federal Reserve Board (*FRB*).[2] The surveys, which oversampled upper income groups, collected detailed information not only for income, saving, and the values of major categories of assets, but also for the amounts of individual stocks held at the beginning of the year. For purposes of this paper, we were able for the first time to use the data on individual stockholdings to estimate capital gains (largely unrealized) on a major and most volatile part of household wealth. As a result, the effect of capital gains on saving during the year can be studied on the basis of a large number rather than a handful of observations.

Our analysis of the survey data indicates that household saving in 1963 was reduced by about \$.02 to \$.04 for every dollar of capital gains on corporate stock during that year, with the precise figure obtained depending on the form of the regression utilized and the nature of the adjustments made to the original *FRB* sample. The bulk of our estimates, which are concentrated in the lower half of the .02 to .04 range, are above the corresponding figures implied by John Arena (1964, 1965), Kul Bhatia, Martin Feldstein, and Feldstein and George Fane, and modestly less than the figure implied by the latest version of the *MPS* model.

While estimates of long-run asset effects on household saving are also provided by our analysis of the 1963 survey data, they are not as stable as the capital gains coefficients. Moreover, as is well known, the long-run asset coefficients in saving regressions based on household survey data are downward biased in absolute value since assets serve as a proxy for savings tastes as well as a measure of resources available for consumption and investment. To obtain definitive insights into the timing and magnitude of asset effects on consumption, it will probably be necessary to collect new panel data on household savings, income, assets, and capital gains. However, even with the cross-section information already available, it is possible to improve on our present knowledge of such effects.

I. Earlier Work

The only extensive use of cross-section data in earlier studies of asset effects on household savings and consumption consisted of the estimation of long-run effects. These effects were generally rather small, even when they had the theoretically expected sign and were statistically significant.[3] They are understated because of differences in household saving tastes which cannot adequately be kept constant in an analysis of single cross-section data.

Earlier time-series studies by Arena (1964, 1965), Bhatia, Feldstein, and Feldstein and Fane included estimates of both long-run and short-run asset effects. All reported either small or statistically insignificant short-run asset effects, with no one-year effect exceeding .019. In contrast, the early studies by Albert Ando and Franco Modigliani indicated asset effects between .04 and .08, with no distinction between short-run and long-run effects, and while their most recent results incorporated in the *MPS* model point to considerably smaller short-term effects, at least for stock holdings, they are still substantially above the estimates reported in the other time-series analyses.[4]

---

[2] A description of these surveys and of the data collected appears in Dorothy Projector and Gertrude Weiss, and Projector.

[3] See, for example, Jean Crockett and Friend (1967), and Projector.

[4] The updated version of the *MPS* model represents revisions incorporated as late as January 1973. As compared with earlier estimates, which did not break down wealth into stocks and other assets, the long-run asset coefficient (assumed to be the same for both forms of assets) did not change appreciably. However, a much lower proportion of the effect on consumption of changes in the value of stock and a much higher proportion of the impact of changes in the value of other assets take place in the first three months.

II. Limitations of New Data

There are several difficulties in extending to the corresponding time-series relationships the results of an analysis of survey data on personal saving, income, capital gains, and assets derived from a single cross-section of households. First, since transitory components of some of these variables are more important in cross-section data, there is a need to separate normal from transitory components. Second, since we are interested in drawing intertemporal conclusions from interpersonal data, tastes effects must be considered. Third, measurement errors are generally larger for cross-section than for aggregate time-series data (see Friend and Stanley Schor). However, for the value of stock assets held by households and the associated capital gains, the cross-section data as provided by the *FRB* are likely to be fully as accurate as the aggregate time-series data in the United States—at least for the high proportion of respondents who reported the number of shares owned of each stock in their portfolios.[5] Moreover, as indicated subsequently, the blown-up *FRB* sample data on saving, income, stock assets, and capital gains are not too different from the corresponding national aggregates, once the sample is adjusted for deficient responses. Fourth, the definition of saving used by the *FRB* differs from the time-series (and customary economic) definition in several respects. The two most important differences are the absence of any deduction for depreciation on owned homes and of any allowance for saving in the form of life insurance. In our statistical results, we have consistently subtracted depreciation from the *FRB* measure of saving, and in part of our analysis we have added back a rough allowance for saving in the form of life insurance.[6] Fifth, while trust accounts are included in the household's net worth, capital gains on stock held in such accounts are not included in the household's capital gains, so that capital gains are somewhat understated and the capital gains effect somewhat overstated.[7]

Since the major contribution of this paper is to make use of the unique *FRB* data on the detailed stock holdings of individual households for deriving new estimates of capital gains effects on saving, it should be noted that the capital gains data, though of relatively high quality, are still subject to some error. Capital gains are estimated from the prices at the beginning and end of the year for individual stocks held by each household at the beginning of the year. Even where respondents correctly reported the number of shares owned of each stock in their portfolios, our estimates of accrued capital gains (or losses) attribute to a household gains which accrued to a stock after it had been sold, while accrued gains on purchases made during the year are excluded. Even so, the error introduced is rather small for individuals who provided data on their individual stock positions.[8]

---

[5] A fairly close correspondence between reported and actual ownership for respondents who give the number of shares owned is indicated in validation tests discussed in Robert Ferber et al. In contrast a recent revision of the estimated market value of outstanding stocks in the United States made as part of the Securities and Exchange Commission (*SEC*) *Institutional Investor Study* showed very little difference between the earlier *SEC* figures and the revised figures for the early 1960's, but a $283 billion or 37 percent upward revision by 1968, most of the discrepancy occurring after 1964.

[6] Depreciation on housing was estimated at 1.5 percent of the initial value of housing on the basis of the 1950 *FRB* "Survey of Consumer Finances." Where the survey definition of saving was expanded to include life insurance, the change in cash surrender value was used as a measure of saving in life insurance.

[7] It was possible to roughly estimate capital gains on the aggregate of stock held in trust accounts for each household reporting such accounts and to redo the analysis on this basis. Fortunately, the capital gains and other coefficients presented in Table 1 were virtually unaffected.

[8] As measured by the *FRB* survey, realized capital gains on securities (which includes some gains on assets

In some cases no identification of specific shareholdings was given, raising more serious questions of data reliability.[9] To guard against significant errors, for much of our analysis the sample used was restricted to those households which either reported no shareholdings or for which identified shareholdings accounted for at least 90 percent of the total value of their reported stockholdings. This restriction reduced the sample by 389 to 1,770 observations. For part of the analysis other restrictions were also employed reducing this sample further. When stock was unidentified, capital gains were estimated at 20 percent for the year.[10] As a result, the capital gain variable contains an additional small random error which would tend to bias somewhat its estimated coefficient towards zero. The sensitivity of the capital gain coefficient to random errors is tested in our statistical analysis.

Finally, the weighting procedures followed are important in the interpretation of the results, because the survey heavily oversampled upper income groups and also because nonrandom subsamples are used in much of our analysis. Roughly 128 weight classes distinguished by income, age, retirement status, and moving status (which indicates whether families moved in 1963) are employed, with each observation assigned a weight to represent a specific number of households in the population. Whenever observations are deleted, the remaining observations are proportionately scaled upward so that the total weight for each class remains unaffected. Should a weight class lose all of its observations, its weight is distributed among the members of a nearby weight class.

III. New Statistical Results

A number of cross-section regressions were estimated from the *FRB* survey data using the general form

$$S = a + bY_N + cY_T + dZ + eA_{-1} + f\,\text{Age} + g\ \text{Family Size} + h\ \text{Occupation}$$

where S is saving for 1963 net of depreciation on owned homes; Y_N, normal disposable income in 1962 and 1963;[11] $Y_T = Y_{63} - Y_N$; Z, 1963 accrued capital gains on stocks;[12] A_{-1} is market value of net worth at the end of 1962. Age and Family Size are continuous variables while Occupation is a dummy taking on the value 1 for households with self-employed heads and 0 for all other households.[13] In some regressions, V_{-1}, the net worth of stocks, and O_{-1}, the net worth of other assets, are substituted for A_{-1}.

The *FRB* survey did collect data on realized capital gains on all securities combined as a global figure for each household, but these figures seemed extremely weak and could not be checked against other data so that in the results presented in this paper no distinction was made between realized and unrealized capital gains.[14] No

---

other than stocks) represent only about 5 percent of the value of accrued capital gains on stocks. Furthermore, gains attributed to common stock which was sold will be offset to a considerable extent by the gains which accrued to those individuals who reinvested the proceeds of their sales.

[9] Ferber et al. found that in these cases the wealthy underreported their holdings whereas the (relatively) poor overstated their holdings.

[10] The composite 1963 New York Stock Exchange (*NYSE*) capital gain was 18.1 percent and the over the counter (*OTC*) gain was 20.4 percent as determined respectively from the New York Stock Exchange Common Stock and National Quotation Board indices.

[11] Normal income was also defined as the expected value of disposable income derived by regressing 1963 household income on the average incomes of each of a number of socio-economic-demographic groups to which the household belonged, with no important changes in the short-run asset effects presented here.

[12] Accrued gains in 1963 are gains reflecting the price changes during that year.

[13] Dummy variables were also introduced for age, distinguishing among household heads who were less than 39 years old, 40 to 59 years, and 60 and over years, without any noteworthy change in regression results.

[14] External sources as well as the survey data indicate that realized capital gains on stock are a small fraction

variable was introduced for accrued capital gains on assets other than stocks since such data were not available from the *FRB* survey. As a result, we were not able to check the intuitively implausible *MPS* result that the effect of an unexpected as well as expected change in value of homes, bonds, and other nonequity assets on household consumption takes place immediately (i.e., in the same quarter). We were, however, able to check the implications of the *MPS* model for the timing pattern of consumption effects flowing from changes in the market value of stock owned.

Theory suggests that the capital gains coefficient d should be between 0 and the negative asset coefficient e.[15] For unanticipated capital gains, the coefficient would be expected to be close to zero; for anticipated gains, close to e. However, even though investors are likely to have some long-run capital gains rate in mind when they invest, short-run capital gains may be almost entirely unanticipated. Since any anticipated capital gains are presumably highly correlated with initial assets (and theoretically would be expected to have the same coefficient), the d coefficient in the saving regressions should reflect mainly the effect of unanticipated gains. We are interested, of course, in both the d and e coefficients, measuring respectively the short-run (same year's unanticipated capital gain) and long-run asset effects on saving.

Unfortunately, there is reason to believe that only the capital gains coefficient is measured with any precision. The assets or net worth coefficient is likely to be substantially downward biased (in absolute value) by tastes effects, since households which have a high propensity to save will have both high savings and high assets. However, the capital gains coefficient is likely to be much less biased by tastes effects since tastes are much more highly correlated with assets than with capital gains. Indeed, when assets as well as capital gains are included in the savings regression, the correlation of capital gains and tastes should be close to zero.

Table 1 presents the major statistical results obtained from the analysis of the *FRB* survey, with data for each household weighted by the appropriate sampling ratio. The definitions of the saving, income, capital gains, and asset variables used in these regressions are those specified by the *FRB* (see Projector) except that depreciation on owned homes was deducted both from saving and assets. While this depreciation adjustment was made to improve conceptually the saving and wealth estimates, it should be noted that the capital gains coefficient was not affected appreciably. The most important remaining deficiency in the measures of saving and assets generally used in Table 1 is that the change in and the level of equity in insurance are not reflected in saving or assets. However, several regressions were computed in which the change in and the level of the cash surrender value of life insurance were added to the saving and asset variables, and one of these regressions is presented in the table. Equation (1) in the table, which covers all 2,159 households in the sample, points to a low depressant effect of capital gains Z and assets A_{-1} on saving, a rather high normal income Y_N effect, and a low transitory income Y_T effect. Only the Y_N and A_{-1} coefficients are statistically significant at the customary 95 percent level, and the goodness of fit ($\overline{R}^2$) for the equation as a whole is quite low, even for ungrouped cross-section data.

Since there are, except for the respondents who give the names and quantities

---

of unrealized gains. See Lieberman for the effects of realized capital gains.

[15] For a theoretical discussion of the signs and values of these parameters, see Friend and Paul Taubman, and Crockett and Friend (forthcoming).

Note: Dependent variable is saving for 1963 net of depreciation on owned homes and in equation (6) is adjusted for saving in the form of life insurance; Y_N, normal income defined as the average of annual disposable income in 1962 and 1963; $Y_T=Y_a-Y_N$; Z, 1963 accrued capital gains on stocks; V_{-1}, the market value of corporate equities at the end of 1962; O_{-1}, the market value of assets other than equities at the end of 1962; A_{-1}, market value of assets or net worth held at the end of 1962; and Age and Family Size are continuous variables while Occupation is represented by a dummy variable taking on the value 1 for households with self-employed heads and 0 for all other households. Figures in parentheses are t-statistics. Dollar variables are measured in thousands of dollars. $\bar{R}^2$ is R^2 adjusted for degrees of freedom. Standard error in ast line is standard error of expected saving conditional on mean values of independent variables.

of individual shares owned, substantial errors in reporting the value of stock assets and in estimating capital gains on stock,[16] the two variables in which we are particularly interested, a second set of regressions, equations (2)–(3), was based on those households which gave satisfactory detail on stock ownership. This second sample consisting of 1,770 households excluded those respondents reporting stock ownership who did not stipulate the amounts of individual stocks held accounting for at least 90 percent of the value of all stock reported owned by the household. Equation (2) is directly comparable to (1), except for the smaller sample, and (3) substitutes the market value of stocks V_{-1} and other assets O_{-1} for total initial assets.

The results of equations (2) and (3) represent an improvement over equation (1), with a moderately higher overall correlation, and with more generally satisfactory regression coefficients. Thus the coefficients of Y_T are now statistically significant and, as would be expected, are higher than those of Y_N. Of special importance for our analysis, the coefficients of Z not only have the theoretically anticipated sign but are significant as well. Of the other economically important variables, the coefficient of A_{-1} is increased somewhat (in absolute value). The substitution of V_{-1} and O_{-1} for A_{-1} gives unreasonable results for the coefficient of O_{-1}, perhaps partly as a reflection of the multicollinearity between V_{-1} and O_{-1} and partly as a reflection of very large random errors in the measurement of O_{-1}. (Of the other socio-economic-demographic variables, none is significant though there is some indication that small families and entrepreneurs save more than other households.)

---

[16] See Ferber et al. Even for respondents giving the number of shares of all stock reported owned, there is some tendency to overstate the size of very small holdings and understate very large holdings, and thus to bias somewhat upward (in absolute value) the coefficient of Z.

To eliminate other apparent sources of error in measuring saving, income, and assets, households which did not pass a number of quality checks were excluded resulting in a reduced sample of 1,195 households, and a new set of regression results is presented in equations (4)–(6). Households were excluded if 1) net worth was negative, 2) normal income was less than $1,000, 3) the absolute level of saving was greater than normal income, and 4) stock assets at the beginning of year had a market value of less than $200,000 and capital gains were in excess of the value of stocks held, or stock assets had a market value of $200,000 or more and capital gains were in excess of half the value of stock held. The first of these exclusions was the most important and the fourth quite unimportant in reducing the sample size. The third is by far the most important exclusion in terms of impact on the regression coefficients.

Equations (4) and (5) for the 1,195 sample are the counterparts of (2) and (3) for the 1,770 sample. It will be noticed that the normal income and asset coefficients are substantially reduced, and the asset coefficient is no longer significant,[17] but that the capital gains coefficients are much less affected. (The occupational dummy variable is now significant or close to significant, with entrepreneurs again saving more than other households.) Equation (6) is the same as (4) except that savings and assets are now expanded conceptually to include the change in and level of the cash surrender value of private life insurance.[18] This provides an approximate measure of household saving which conforms more closely to the measure used in the aggregate national income statistics and econometric models. The adjustment of saving and assets for private life insurance does not significantly affect the regression coefficients either here or in other equations tested, though the capital gains coefficient is somewhat lowered.

To eliminate one last potentially significant source of error in measuring assets and capital gains, households which reported owning no stock were excluded from the preceding sample of 1,195 households, resulting in a much smaller sample of 303 households. The reason for this exclusion is that validation checks suggest that a number of households reporting no stock do in fact own some (see Ferber et al.). On the other hand, though the quality of the sample is further improved, its size and representativeness are greatly reduced and the resulting sample is biased in favor of households which have a propensity for saving in the form of stock. While the mean saving, income, net worth, and capital gains of households are affected only moderately as the sample is reduced in size to 1,195 households, the mean market value of stock held and capital gains (though not saving and income) are increased substantially as the sample is further reduced to 303 households.

In equation (7), the 303 sample households are weighted using the 128 weight classes which result from the *FRB* survey weighting procedures. In view of the small size of the remaining sample relative to the number of weight classes, obviously few or no observations are included in many of the classes if the *FRB* weighting procedures are followed. To handle this problem, the number of weight classes was reduced to 12 based upon normal income. The Y_N weights are internally generated by adding up the *FRB* weights of all the individual households within the larger normal income classes. Class sizes were chosen so as to contain an approxi-

[17] In one equation, the stock assets coefficient V_{-1} is significant but has the wrong sign.

[18] It would be preferable to use equity instead of cash surrender value, but the data are not available in the *FRB* survey.

mately equal number of observations. It is noteworthy that when the 303 sample is weighted by normal income, the blown-up survey estimates of mean saving and income are reasonably close to the external figures obtained from time-series data, which is also true for the larger samples. However, the capital gains and market value of stock estimates from the 303 sample are appreciably larger than the corresponding external figures,[19] whereas the estimates from the larger samples are substantially smaller than the external figures. As a result, the capital gains effects indicated by the 1,195 and larger samples might be expected to be somewhat overstated while the reverse would be true for the 303 sample.

Fortunately, when the Y_N weights were used in equation (8), the statistical results were not too different from those obtained in the corresponding equation (4) based on the 1,195 sample. The most obvious difference between equations (7) and (8) or (4) is in the correlation, with $\bar{R}^2$ for (7) much higher than for the others. However, little confidence can be placed in (7) in view of the large weights ascribed to a small number of statistically biased observations in many of the 128 weight classes and the highly questionable figure for mean saving.

Finally, since the first eight equations in Table 1 all display significant heteroscedasticity in the residuals so that the t-values are overstated, four other equations derived from the 1,195 sample have been added (equations (9)–(12)) which correct for this problem by dividing S, Y_N, Y_T, Z, A_{-1}, and the constant term either by $A_{-1}^{.25}$ (equations (9) and (10)) or by $Y_N^{.25}$ (equations (11) and (12)).[20] Equations (9) and (11) like the first eight equations represent weighted regressions, while (10) and (12) are unweighted. The first three of these four equations almost completely eliminate heteroscedasticity in the residuals while the last, equation (12), substantially reduces heteroscedasticity but it is still statistically significant. The estimated capital gains effect on saving in these four regressions is somewhat lower on average than in the corresponding equation (4) which is weighted but not adjusted for heteroscedasticity, but the differences are probably not statistically significant.

Since age is assigned an important role in saving by life-cycle theories, equation (4) which is based on the 1,195 sample was recomputed for each of five age groups and the results presented in Table 2. The capital gains coefficients show substantial variability, but are never significant. Hence, they are not as satisfactory as the more aggregate results. However, all the capital gains coefficients have the correct sign and the variability may well reflect the small size of the subsamples.[21]

The estimation of other mathematical forms did not change the range of Z coefficients from those indicated above. As suggested earlier, measurement error would be expected to introduce some downward bias in the coefficient of Z, but this bias is likely to be small at least in the 1,195 and 303 samples.[22]

---

[19] Mean saving (exclusive of insurance), family disposable income, and capital gains on stock for the 303 sample were $422, $5,720, and $1,911, respectively, per household. Multiplying these figures by 57.9 million households (Projector, p. 320) provides 1963 aggregate personal saving and family disposable income fairly close to the corresponding national accounts totals, but aggregate capital gains on stock appreciably higher than the product of the *SEC* total of individuals' stock holdings and the 20 percent estimated percentage capital gain.

[20] This is equivalent to assuming that for different values of these independent variables the ratio of the original variance of residuals to $A_{-1}^{.5}$ or $Y_N^{.5}$ is constant.

[21] When the sample households are classified into three instead of five age groups, the coefficient of capital gains for the middle age group, viz., 40–59 years for the age of household head, is statistically significant (with a coefficient of $-.039$ and t-value of 4.24). The omission of the age variable from either the five or three age group regressions has virtually no effect on the Z coefficients, nor does the substitution of dummy age variables (intercept and slope) for age as a continuous variable.

[22] The sensitivity of the Z coefficient to measurement error was tested by adding to Z a random component

TABLE 2—HOUSEHOLD SAVINGS REGRESSION BY AGE OF HEAD

Age of Household Head	Constant	Y_N	Y_T	Z	A_{-1}	Age	Family Size	Occupation	$\bar{R}^2$
−34	−2.10	.20	.38	−.165	.018	.048	−.034	.04	.236
	(−2.70)	(4.57)	(3.65)	(−.26)	(1.81)	(1.57)	(−.50)	(.08)	
35–44	3.78	.04	.23	−.034	−.001	−.092	−.035	1.59	.098
	(1.68)	(1.07)	(2.18)	(−1.62)	(−.16)	(−1.76)	(−.39)	(3.00)	
45–54	.63	.12	.33	−.039	−.003	−.009	−.143	.71	.049
	(.22)	(3.12)	(2.49)	(−.79)	(−1.19)	(−.15)	(−1.50)	(1.28)	
55–64	−.18	.11	.20	−.003	.004	−.001	−.014	−.90	.173
	(−.05)	(3.02)	(2.29)	(−.18)	(3.36)	(−.02)	(−.13)	(−1.44)	
65+	.95	.11	1.15	−.010	−.003	−.013	−.065	−.84	.161
	(.53)	(2.47)	(6.00)	(−.89)	(−1.09)	(−.56)	(−.56)	(−.99)	

Note: See Table 1 for explanation of symbols.

Although a comparison of three of our coefficient estimates—Z, V_{-1}, and O_{-1}—may be made with the *MPS* model, those of V_{-1} and O_{-1} are likely to be substantially biased downward (in absolute value) as a result of the impact of tastes, as noted earlier. For this reason, the fact that the coefficients of V_{-1} and O_{-1} in the *MPS* model are substantially larger than those provided by the analysis of survey results is not significant evidence that the *MPS* results are biased upward.

In contrast, the coefficients of Z in the analysis of 1963 survey results are likely to be little affected by tastes effects. The Z coefficients estimated from the survey regressions, ranging from −.015 to −.041, may be compared with corresponding estimates of −.040 for the last published version of the *MPS* model, −.032 from the latest unpublished version, and much lower figures from other time-series regressions.[23] Thus, the *FRB* survey results suggest that the latest *MPS* estimate of the first year's effect of a change in the value of stock assets on saving and consumption is not far off from the true figure though it may be a little on the high side, while the corresponding effects implied by most other time-series results seem too low.

---

normally distributed with mean zero and standard deviation $k\sigma_t$ where k varied between .1 and .5 and σ_t, the standard deviation of capital gains, is $13,701. Five simulations of equation (4) of Table 1 were run for each value of k. For k equal to .1 the mean value of the Z coefficient was −.028 with a standard deviation of .00049. The corresponding figures were −.022 and .00148 for $k=.4$, and −.020 and .00163 for $k=.5$. At least for the 1,195 and 303 sample sizes, we believe the data to be measured with sufficient accuracy that k is likely to be well under .5.

[23] The estimate for the impact of unanticipated capital gains on saving in the *MPS* model was obtained by assuming that the *MPS* quarterly capital gains coefficients are equal to a weighted combination of the fully anticipated *MPS* wealth effect (.0544 in the latest version of the model) and the unknown unanticipated capital gains effects. The effect in subsequent periods of unanticipated capital gain in any quarter is the product of the weight of unanticipated gains in that quarter multiplied by the appropriate quarterly coefficient of such gains in the sequence of coefficients reflecting adjustment of households to the new level of assets. This formulation leads to five unknowns if the weight of unanticipated capital gains is assumed constant (the four quarterly unanticipated capital gains coefficients and the weight of unanticipated—or anticipated—capital gains) but only four equations (one for each *MPS* quarterly coefficient). If the effect of contemporaneous capital gains is zero, an upper bound of .3 is found for the weight of anticipated capital gains in the latest version of the *MPS* model. Assuming values between 0 and .3 for the weight of anticipated capital gains results in a narrow bracketed solution for the quarterly impact of unanticipated capital gains permitting use of the midpoints. The midpoints of the bracket for each quarter may then be applied to the percentage of 1963 capital gains which accrued during each quarter to estimate the impact of unanticipated capital gains on 1963 savings. A simple average of the *NYSE* and *OTC* composite index was used to calculate the percentage of 1963 capital gains which accrued during each quarter.

However, it should be noted that the time-series estimates represent an average over a period of years while the survey results presented here are for a single year only.

To obtain a more definitive result for the first year's effect in general, survey data for other periods would be needed, and to obtain a complete answer to the long-term as well as short-term time sequence of asset effects would require panel survey data. The statistical findings in this paper not only strongly support the inclusion of capital gains, and implicitly net worth, in the consumption function, but also indicate that survey data constitute an unusually promising source of information for quantifying the time-sequence of asset effects on saving and consumption.

Pure Traded Intermediate Products and The Heckscher-Ohlin Theorem

By ALBERT G. SCHWEINBERGER*

In a recent paper, Raveendra Batra and Francisco Casas introduced a nontraded intermediate product into the basic Heckscher-Ohlin trade model. This is an important step forward, because nontraded intermediate products (as well as intermediate products in general) must be of great quantitative significance in the real world. Traditionally, intermediate products have for a long time been ignored in trade theory. When traded intermediate products were finally taken account of, it seemed that most of trade theory could still be applied with only rather minor changes. This initial "optimism" has now given way to a much more cautious attitude. It has been realized that one of the main reasons why it seemed at first sight that most results of trade theory are still valid when intermediate products are allowed for is to be found in the rather special way in which intermediate products were introduced:

1) Intermediate input coefficients were assumed to be fixed.
2) The intermediate products were of the Leontief kind, i.e., they were products which are used for production as well as for final consumption purposes.

The paper by Batra and Casas is exceptional in that it introduces pure intermediate products into the Heckscher-Ohlin framework. One of the key results of their paper is that the Heckscher-Ohlin theory remains valid in this new model only if factor intensities are interpreted in terms of total original input requirements. If only direct original factor input requirements are taken into account, the Heckscher-Ohlin model may break down. The present paper attempts to throw some light on the validity of the Heckscher-Ohlin theorem when the model contains pure *traded* intermediate products. Furthermore, the assumption of fixed intermediate input coefficients, which is so prominent in most trade theory (for example, effective protection theory), is also relaxed.

The paper is divided into two sections. In Section I, a model is analyzed where the number of produced products (for the world as a whole) is greater than the number of scarce primary factors. In Section II, both countries are assumed to produce one final commodity and one pure intermediate product in the original pretrade equilibrium and under conditions of universal free trade.

I. The Model

At first sight it would seem that the introduction of pure traded intermediate products into a traditional two original factor Heckscher-Ohlin trade model, where both final commodities are produced under constant returns to scale, is quite impossible. The reason for this is that in a traditional Heckscher-Ohlin model the trading pattern is determined by the pretrade relative prices and it is assumed that both countries produce all commodities in the

---

* University of East Anglia. I am indebted to an unknown referee for helpful comments and criticism. An early version of this paper was presented to the International Economics Study Group at the London School of Economics.

pretrade and in the free trade equilibrium. But with three traded commodities being produced in each country, it follows that the traditional assumptions of the Heckscher-Ohlin theorem imply that under free trade factor prices are equalized. In what follows it has been assumed that free trade does not result in an equalization of factor prices. Given the assumption of identical production functions and constant returns to scale, it would therefore seem that allowing for two final commodities, two original factors of production, and one traded intermediate product, the following set of functions cannot be independent:

$$\begin{aligned} a_{11}p_1 + a_{21}p_2 + a_{m1}p_I &= q_1 \\ a_{12}p_1 + a_{22}p_2 + a_{m2}p_I &= q_2 \\ a_{13}p_1 + a_{23}p_2 \qquad\quad &= p_I \end{aligned}$$

where a_{ij} = primary factor input coefficients
a_{mj} = intermediate input coefficients
p = primary factor prices
q = free trade equilibrium final output prices
p_I = the free trade equilibrium price of the intermediate product

Let q and p_I be given. It then follows that the set of three cost functions cannot be independent as long as cost functions, and therefore production functions, are homogeneous of degree 1. At this point one may be tempted to give up. But there is a way out. While it follows from the above that both countries cannot normally produce all commodities in a trading equilibrium, it does not follow that the world as a whole may not be producing all three commodities. If primary factor endowments are different in the two countries, there is no reason at all why there should not be specialization between countries in the trading equilibrium. It seems likely that the assumption of nonspecialization between countries, which is so prevalent in much of the literature on trade theory, is one of its main drawbacks for the simple reason that it is specialization rather than nonspecialization which one appears to observe in the real world. Probably the main reason why nonspecialization has almost always been assumed is one of analytical convenience. Since the rise of concave programming, a technique of analysis has become available which I hope to show can easily cope with the problems of particular specialization patterns.

It is therefore suggested that the assumption of nonspecialization of the traditional Heckscher-Ohlin model be dropped, but the assumption of identical production functions retained. It follows from this that in general factor prices will not be equalized between countries, because if the specialization pattern of production is different between the two countries, one is solving two different sets of cost functions. It has long been observed in practice that primary factor prices are not equalized by trade. The traditional conclusions have been that either production functions are not identical or factor intensity reversals occur over the relevant range of factor prices. Perhaps a much more important reason for the nonequalization of primary factor prices by free trade is to be found in the presence of particular specialization patterns between countries.

In order to allow for a particular specialization pattern to emerge in free trade equilibrium, one has to drop the traditional approach of cost functions which are all fulfilled and rewrite the problem as a non-linear program. Factor prices in the two countries will be determined as the optimal solution vectors of the two following non-linear programs:

Country 1: Min $p_1K + p_2L$

subject to

$$\begin{aligned} a_{11}p_1 + a_{21}p_2 + a_{m1}p_I &\geq q_1 \\ a_{12}p_1 + a_{22}p_2 + a_{m2}p_I &\geq q_2 \\ a_{13}p_1 + a_{23}p_2 \qquad\quad &\geq p_I \\ p_1,\ p_2 &\geq 0 \end{aligned}$$

where K and L are primary factor endowments in country 1.

$$\text{Country 2:}\quad \text{Min } p_1K' + p_2L'$$

$$\begin{aligned} \text{subject to}\qquad & a_{11}p_1 + a_{21}p_2 + a_{m1}p_I \geq q_1 \\ & a_{12}p_1 + a_{22}p_2 + a_{m2}p_I \geq q_2 \\ & a_{13}p_1 + a_{23}p_2 \qquad\qquad \geq p_I \end{aligned}$$

where K' and L' are primary factor endowments in country 2.

Perhaps it should be made explicit that under constant returns to scale both these programs should in general be soluble, because the variables of all three constraints are primary factor prices only. From inspection of the two programs, it follows that the world as a whole will produce all three commodities with primary factor prices not being equalized by free trade, if and only if there is a minimum difference between the factor endowment vectors of the two countries (given that production functions are identical). If factor endowment vectors do not differ by this minimum amount (this will be clarified later), particular specialization patterns between countries could not emerge unless production functions are different between countries. In the present analysis the assumption of identical production functions is retained. There are three more assumptions which have to be made in order to ensure that in this model primary factor prices are uniquely determined for given primary factor endowments and prices q_1, q_2, and p_I:

1: All production and therefore cost functions are homogeneous of degree 1.
2: All unreduced cost functions are concave.
3: Each country produces two products.

Assumption 2 implies that:

$$(1)\quad \frac{\partial a_{13}}{\partial p_1} \leq 0 \qquad \begin{vmatrix} \dfrac{\partial a_{13}}{\partial p_1} & \dfrac{\partial a_{13}}{\partial p_2} \\ \dfrac{\partial a_{23}}{\partial p_1} & \dfrac{\partial a_{23}}{\partial p_2} \end{vmatrix} \geq 0$$

$$(2)\quad \frac{\partial a_{1i}}{\partial p_1} \leq 0 \qquad \begin{vmatrix} \dfrac{\partial a_{1i}}{\partial p_1} & \dfrac{\partial a_{1i}}{\partial p_2} \\ \dfrac{\partial a_{2i}}{\partial p_1} & \dfrac{\partial a_{2i}}{\partial p_2} \end{vmatrix} \geq 0$$

$$\begin{vmatrix} \dfrac{\partial a_{1i}}{\partial p_1} & \dfrac{\partial a_{1i}}{\partial p_2} & \dfrac{\partial a_{1i}}{\partial p_I} \\ \dfrac{\partial a_{2i}}{\partial p_1} & \dfrac{\partial a_{2i}}{\partial p_2} & \dfrac{\partial a_{2i}}{\partial p_I} \\ \dfrac{\partial a_{mi}}{\partial p_1} & \dfrac{\partial a_{mi}}{\partial p_2} & \dfrac{\partial a_{mi}}{\partial p_I} \end{vmatrix} \leq 0$$

where $i = 1, 2$.

We now want to prove that the conditions stated immediately above imply that the cost functions of assumption 2

$$q_i = q_i(p_1, p_2, p_I) \qquad i = 1, 2$$

are concave in the variables p_1 and p_2 if p_I is fixed at some level p_I^0. In fact, the proof is very easy. Note that a cost function is concave if, for given traded final output and intermediate product prices, $d^2p_2/dp_1^2 \geq 0$. One immediately obtains (assuming cost minimization):

$$\frac{dp_2}{dp_1} = -\frac{a_{11}}{a_{21}}$$

so that

$$\frac{d^2p_2}{dp_1^2} \geq 0, \qquad \text{for } p_I = p_I^0$$

follows immediately from the conditions stated under assumption 2.

Proceeding similarly with the cost functions of final commodity 2 and the intermediate product, the solution of the nonlinear program (for given q_1, q_2, and p_I) may be illustrated diagrammatically as in Figure 1.[1] After plotting the cost functions, the first step is to derive the feasible set of solution values p_1 and p_2. Making the assumptions 1, 2, and 3 stated above, it can readily be shown that the feasible constraint set must be convex (in Figure 1 it is the shaded area). Clearly, primary factor prices will be uniquely determined for given original factor endowments, provided that the constraint set is convex and that each country produces two products. It should be emphasized at this point that the cost functions, as shown in Figure 1, represent a rather special case. As can be seen, the boundary of the feasible set of original factor price solutions shows two vertices (A and B). The right- and left-hand derivatives dp_2/dp_1 at A and B indicate the limits within which variations of primary factor endowment ratios between the two countries are compatible with nonspecialization in production and an equalization of primary factor prices (assuming that free trade equilibrium prices q_1, q_2, and p_I remain unchanged).

---

[1] It should be carefully noted that the figure has been drawn on the assumption that one country is in equilibrium at the vertex A and the other at B, so that factor prices are not equalized by trade. If factor prices were equalized by trade, both countries could normally produce all three commodities. The necessary and suffi-

To discuss the validity of the Heckscher-Ohlin theorem when the assumption of nonspecialization is relaxed, the attention of the reader is drawn to Figure 1. Before embarking upon a more detailed analysis, it should be stated that the K/L ratios for final commodities 1 and 2 and the intermediate product for various factor price ratios (p_2/p_1) can quite easily be read off Figure 1. It may be shown, for example, that the slope of the q_1 curve at any point is equal to the direct K/L ratio used in the production of final commodity 1:

$$dq_1 = a_{m1}dp_I + a_{11}dp_1 + a_{21}dp_2$$

but $dq_1 = 0$ and $dp_I = 0$. Therefore, it follows that $dp_2/dp_1 = -a_{11}/a_{21}$, and similarly with the cost function of the other final

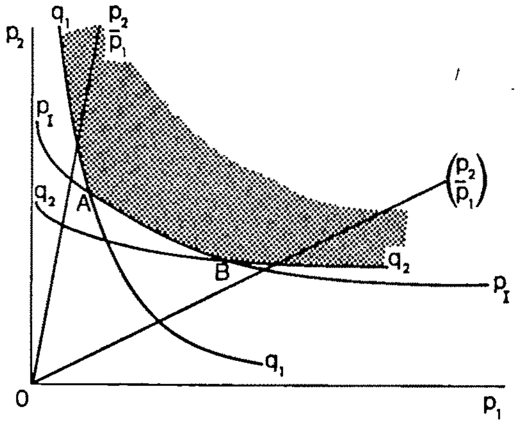

FIGURE 1

commodity and the traded intermediate product. We are concerned here only with the validity of the Heckscher-Ohlin theorem when factor endowments and demand functions are such that one country is in equilibrium at A and the other at B. It should also be noted that Figure 1 has been drawn in such a way that within the relevant primary factor price ratios (p_2/p_1) and p_2/p_1, there is a clearly defined ranking of direct primary factor intensities, such that $(K/L)_1 > (K/L)_I > (K/L)_2$. (It should perhaps be added here that whenever a pair of cost functions has at most one point of intersection within the relevant range of primary factor prices, no factor intensity reversals can occur. Also, if the ranking is as shown on Figure 1, a ranking of final commodities according to direct factor intensities must always be the same as a ranking according to total factor intensities. For a proof, see Batra and Casas.)

Let country 1, which is the relative capital abundant economy, be in equilibrium at A and let the other country be in equilibrium at B. There is now obviously no problem with the Heckscher-Ohlin theorem correctly predicting the trading pattern of final commodities. The country with the greater capital endowment will obviously export the more capital intensive final commodity. But both

---

cient conditions for the latter to be the case are: the endowment ratios of both countries must lie between any given pair of direct capital/labor ratios used in the production of the same two products; and both endowment ratios must also lie between the *total* capital/labor ratios of the two final commodities.

countries produce the intermediate product and it has to be proved that country 1 will export it, in order to establish the validity of the Heckscher-Ohlin theorem. For this purpose, in trading equilibrium, world supply must be equal to world demand for every commodity. World demand for the intermediate product is given by $a_{m1}C_1 + a'_{m2}C'_2$ and world supply by C_I and C'_I (where the primes denote country 2). If the intermediate product is to be imported by country 2, one must have

$$a_{m1}C_1 - C_I < 0$$

The factor market equilibrium conditions in country 1 are:

$$a_{11}C_1 + a_{1I}C_I = K$$

$$a_{21}C_1 + a_{2I}C_I = L$$

Solving for C_1 and C_I and substituting into $a_{m1}C_1 - C_I$, one obtains:

$$a_{m1}C_1 - C_I = \frac{\begin{vmatrix} K & a_{m1}a_{1I} + a_{11} \\ L & a_{m1}a_{2I} + a_{21} \end{vmatrix}}{|a|} < 0$$

As pointed out above, if the direct factor intensity ratio of the intermediate product is nonextremal, i.e., lies between the direct factor intensity ratios of the two final commodities, there is no problem with regard to the interpretation of the Heckscher-Ohlin theorem referring either to direct or total factor intensities of final commodities. In the traditional Heckscher-Ohlin model it is assumed that the capital/labor ratios of both countries lie within the convex cones of the capital/labor ratios used in the production of both commodities. If it is assumed that the same holds in the present model, i.e., total capital/labor ratio used in the production of commodity 1 > endowment ratios of both countries > total capital/labor ratio used in the production of commodity 2, it immediately follows that $a_{m1}C_1 - C_I < 0$, or, verbally, that country 1 (the capital abundant country) will export the intermediate product and country 2 (the labor abundant country) will import it. It must be emphasized that this result holds only if the endowment ratios of the two countries lie between the total original factor intensity ratios of final commodities. Clearly, it does not follow from $a_{11}/a_{21} > a_{1I}/a_{2I} > a_{12}/a_{22}$ that $K/L < (a_{11} + a_{m1}a_{1I})/(a_{21} + a_{m1}a_{2I})$, where K/L is the endowment ratio of the relatively capital abundant country, even though $a_{11}/a_{21} > K/L > a_{1I}/a_{2I}$ is assumed to hold, as shown in Figure 1.

If the total capital/labor ratio used in the production of final commodity 1 is smaller in the capital abundant country than the endowment ratio, it follows that the intermediate product will be imported rather than exported by the capital abundant country. But, on the basis of the Heckscher-Ohlin theorem, one would expect that the relatively capital abundant country would export the intermediate product, because it is more capital intensive (at any given factor price ratio) than final commodity $2(a_{1I}/a_{2I} > a_{12}/a_{22})$.

It would therefore seem that if the nonspecialization assumption is dropped, the Heckscher-Ohlin theorem is rehabilitated in the sense that it would seem to be suitable not only to predict the trading pattern when trade is confined to final commodities, but also in the more general case, when trade also takes place in intermediate products (provided that the endowment ratios of both countries lie between the total primary factor intensity ratios used in the production of the two final commodities).

Unfortunately, this conjecture is not correct, as may be shown again by means of Figure 1. For this purpose, it is convenient to change the labelling of Figure 1 as follows: the intermediate product is now the most capital intensive commodity and final commodity 1 is less capital intensive than the intermediate product, but more capital intensive than final commodity 2. All this amounts to is to exchange the symbols q_1 and p_I on Figure 1. It is again assumed that over the relevant range of factor price ratios p_2/p_1, no factor intensity reversals occur, i.e., any pair of cost functions has at most one point of intersection. Again, assume that country 1 is in equilibrium at A and country 2 at B. Both countries now produce commodity 1 and country 1 also produces the intermediate product which it definitely will be exporting to country 2. Country 2 produces final commodities 1 and 2 and, given the assumption of nonspecialization in consumption, it follows that country 2 will export commodity 2.

Clearly, the Heckscher-Ohlin theorem is successful in so far as the capital abundant economy exports the most capital intensive product and the more labor abundant economy exports the most labor intensive commodity. The problem is only whether, on the basis of the Heckscher-Ohlin theorem, one can predict whether final commodity 1 is going to be exported or imported by country 1. It appears that the Heckscher-Ohlin theorem is not capable of answering this question. Even if it is assumed as usual that demand patterns are identical between countries and the proportions in which final commodities are demanded are independent of income levels (which are bound to be different in the present example because primary factor prices are not equalized by trade and, of course, factor endowments are different), there is no reason why the labor abundant economy should not export the final commodity, which is relatively more capital intensive (relative to the other final commodity).

To summarize the results of Section I: if it is assumed that no factor intensity reversals occur between any pair of the three products, the Heckscher-Ohlin theorem is completely successful in predicting the trading pattern only if the capital/labor ratio of the intermediate product is nonextremal in the sense that it lies between the direct capital/labor ratios of the final commodities and if the two factor endowments lie between the total primary factor intensity ratios used in the production of both final commodities.

II. Pure Traded Intermediate Products and the Traditional Heckscher-Ohlin Theorem

The main assumptions of the analysis that follows are:

1: The home and foreign countries both produce one final commodity and one pure intermediate product in the original pretrade equilibrium under conditions of universal free trade.

2: The final commodity is considered to be relatively capital intensive and there are two primary factors of production which are always fully employed.

The model is as follows:

a) Factor market equilibrium conditions:

$$a_{11}C_1 + a_{1I}C_I = K$$

$$a_{21}C_1 + a_{2I}C_I = L$$

a_{ij} = primary factor input coefficients (where $j = 1, I$)

$K; L$ = factor endowments,

C_1 = supply of final commodity

C_I = supply of intermediate product

The final commodity is capital intensive and this implies:

$$\begin{vmatrix} a_{11} & a_{1I} \\ a_{21} & a_{2I} \end{vmatrix} > 0$$

b) Cost functions:

$$a_{11}p_1 + a_{21}p_2 + a_{m1}p_I = q_1$$

$$a_{1I}p_1 + a_{2I}p_2 = p_I$$

$p_1; p_2$ = primary factor prices

p_I = price of the intermediate product

q_1 = price of the final commodity
q_1 = numeraire

c) Product market equilibrium condition:

$a_{m1}C_1 = C_I$
a_{m1} = the produced factor input coefficient

The set of equations a), b), and c) represents a closed economy. One wants to find out whether an exogenous increase in $K(L=L_0)$ will lead to a rise or a fall in the price of p_I, depending upon the sign of the determinant

$$\begin{vmatrix} a_{11} & a_{1I} \\ a_{21} & a_{2I} \end{vmatrix}$$

A. *A Very Special Case: Fixed Intermediate Input Coefficients*

If intermediate input coefficients are fixed, the Heckscher-Ohlin theorem can be proved without any difficulty at all. It can easily be seen from an inspection of the set of the factor market equilibrium conditions and cost functions that the following homogeneous, differentiable supply functions, defined for a convex production possibility set $S(C_1, C_I)=0$ with values added and factor endowments as their arguments, are implied:

$$C_1 = C_1(q_1 - a_{m1}p_I, p_I, K, L)$$
$$C_I = C_I(q_1 - a_{m1}p_I, p_I, K, L)$$

Therefore:

$$C_I(q_1 - a_{m1}p_I, p_I, K, L) = a_{m1}C_1(q_1 - a_{m1}p_I, p_I, K, L)$$

The model can be reduced to one equation in one variable p_I. In order to establish the validity of the Heckscher-Ohlin theorem, the last equation is differentiated totally with respect to K.

Solving for dp_I/dK, one obtains:

$$\frac{dp_I}{dK} = \frac{\dfrac{\partial C_1}{\partial K}a_{m1} - \dfrac{\partial C_I}{\partial K}}{\dfrac{\partial C_I}{\partial p_I} - \left(a_{m1}\dfrac{\partial C_I}{\partial pv_1} + a_{m1}\dfrac{\partial C_1}{\partial p_I}\right) + a_{m1}^2\dfrac{\partial C_1}{\partial pv_1}}$$

where $pv_1 = q_1 - a_{m1}p_I$

From the fact that national income may be written as a convex function of values-added $(q_1 - a_{m1}p_I, p_I)$, it follows that the denominator is positive. It can also be readily ascertained that the Rybczynski theorem must hold in the present model, i.e., an increase in the capital endowment (for fixed prices) will bring about an increase in the output of the capital intensive commodity and a decrease in the output of the other product. From

$$\begin{vmatrix} a_{11} & a_{1I} \\ a_{21} & a_{2I} \end{vmatrix} > 0$$

it follows that $\partial C_1/\partial K > 0$ and $\partial C_I/\partial K < 0$, so that the economy with the greater capital endowment will definitely have a comparative advantage in whichever product is relatively capital intensive.

B. *The Assumption of Fixed Intermediate Input Coefficients Relaxed*

The problem now becomes considerably more complicated. The method of solution is to derive three equations in the following three variables: $d\ log\ C_1/d\ log\ K$; $d\ log\ C_2/\ d\ log\ K$; and $d\ log\ p_I/d\ log\ K$ from the set of equations under a), b), and c) given above.

Differentiating first totally the cost functions with respect to K, one obtains:

$$\alpha_{11}\frac{d\log p_1}{d\log K} + \alpha_{21}\frac{d\log p_2}{d\log K} = -\alpha_{m1}\frac{d\log p_I}{d\log K}$$

$$\alpha_{1I}\frac{d\log p_1}{d\log K} + \alpha_{2I}\frac{d\log p_2}{d\log K} = \frac{d\log p_I}{d\log K}$$

$$\text{where } \alpha_{ij} = \frac{a_{ij}p_i}{\text{product price}}$$

Solving, we obtain:

$$\frac{d\,log\,p_1}{d\,log\,K} = \frac{(-\alpha_{m1}\alpha_{2I} - \alpha_{21})}{|\alpha|}\,\frac{d\,log\,p_I}{d\,log\,K}$$

and

$$\frac{d\,log\,p_2}{d\,log\,K} = \frac{(\alpha_{11} + \alpha_{1I}\alpha_{m1})}{|\alpha|}\,\frac{d\,log\,p_I}{d\,log\,K}$$

where $|\alpha|$ is the determinant of cost share ratios. Further below let $a_1 = (-\alpha_{m1}\alpha_{2I} - \alpha_{21})/|\alpha|$ and $a_2 = (\alpha_{11} + \alpha_{1I}\alpha_{m1})/|\alpha|$. Differentiating totally the factor market equilibrium conditions with respect to K, we obtain:

$$b_{11}\frac{d\,log\,C_1}{d\,log\,K} + b_{1I}\frac{d\,log\,C_I}{d\,log\,K} = 1 - b_{11}\frac{d\,log\,a_{11}}{d\,log\,K} - b_{1I}\frac{d\,log\,a_{1I}}{d\,log\,K}$$

$$b_{21}\frac{d\,log\,C_1}{d\,log\,K} + b_{2I}\frac{d\,log\,C_I}{d\,log\,K} = - b_{21}\frac{d\,log\,a_{21}}{d\,log\,K} - b_{2I}\frac{d\,log\,a_{2I}}{d\,log\,K}$$

where b_{ij} = original factor allocation ratios, for example, $b_{11} = a_{11}C_1/K$. Now

$$\frac{d\,log\,a_{11}}{\partial\,log\,K} = \frac{\partial\,log\,a_{11}}{\partial\,log\,p_1}\,\frac{d\,log\,p_1}{d\,log\,K} + \frac{\partial\,log\,a_{11}}{\partial\,log\,p_2}\,\frac{d\,log\,p_2}{d\,log\,K} + \frac{\partial\,log\,a_{11}}{\partial\,log\,p_I}\,\frac{d\,log\,p_I}{d\,log\,K}$$

$$\frac{d\,log\,a_{1I}}{d\,log\,K} = \frac{\partial\,log\,a_{1I}}{\partial\,log\,p_1}\,\frac{d\,log\,p_1}{d\,log\,K} + \frac{\partial\,log\,a_{1I}}{\partial\,log\,p_2}\,\frac{d\,log\,p_2}{d\,log\,K}$$

and now let

$$b_{11}\frac{d\,log\,a_{11}}{d\,log\,K} + b_{1I}\frac{d\,log\,a_{1I}}{d\,log\,K} = A_{11}\frac{d\,log\,p_1}{d\,log\,K} + A_{12}\frac{d\,log\,p_2}{d\,log\,K} + A_{1I}\frac{d\,log\,p_I}{d\,log\,K}$$

where

$$A_{11} = b_{11}\frac{\partial\,log\,a_{11}}{\partial\,log\,p_1} + b_{1I}\frac{\partial\,log\,a_{1I}}{\partial\,log\,p_1} < 0$$

$$A_{12} = b_{11}\frac{\partial\,log\,a_{11}}{\partial\,log\,p_2} + b_{1I}\frac{\partial\,log\,a_{1I}}{\partial\,log\,p_2} > 0$$

(because complementarities between factors are ruled out by assumption) and

$$A_{1I} = b_{11}\frac{\partial\,log\,a_{11}}{\partial\,log\,p_I} > 0$$

Making use of these new definitions and the expressions for $d\,log\,p_1/d\,log\,K$ and $d\,log\,p_2/d\,log\,K$, the differentiated factor market equilibrium conditions may be rewritten as:

$$(3)\quad b_{11}\frac{d\,log\,C_1}{d\,log\,K} + b_{1I}\frac{d\,log\,C_I}{d\,log\,K} + (A_{11}a_1 + A_{12}a_2 + A_{1I})\frac{d\,log\,p_I}{d\,log\,K} = 1$$

$$(4)\quad b_{21}\frac{d\,log\,C_1}{d\,log\,K} + b_{2I}\frac{d\,log\,C_I}{d\,log\,K} + (A_{21}a_1 + A_{22}a_2 + A_{21})\frac{d\,log\,p_I}{d\,log\,K} = 0$$

where A_{21}, A_{22}, and A_{2I} are defined in complete analogy to A_{11}, A_{12}, and A_{1I}, and we know that $A_{21} > 0$, $A_{22} < 0$, and $A_{2I} > 0$.

The third equation is obtained by totally differentiating the product market equilibrium condition:

$$\frac{d\,log\,C_1}{d\,log\,K} - \frac{d\,log\,C_I}{d\,log\,K} + \left(\frac{\partial\,log\,a_{m1}}{\partial\,log\,p_1}a_1 + \frac{\partial\,log\,a_{m1}}{\partial\,log\,p_2}a_2 + \frac{\partial\,log\,a_{m1}}{\partial\,log\,p_I}\right)\frac{d\,log\,p_I}{d\,log\,K} = 0$$

Solving for $d\,log\,p_I/d\,log\,K$, one obtains for the numerator: -1 and for the denominator:

$$a_1\Big(A_{21} - A_{11}\Big) + a_2\Big(A_{22} - A_{12}\Big) +$$

$$A_{2I} - A_{1I} + \left(\frac{\partial \log a_{m1}}{\partial \log p_1} a_1 + \frac{\partial \log a_{m1}}{\partial \log p_2} a_2 + \frac{\partial \log a_{m1}}{\partial \log p_I}\right) |b|$$

The problem now is to find out whether a definite sign can be derived for $d \log p_I / d \log K$, given that $|\alpha| > 0$ (the final commodity is capital intensive) and given that $a_1 < 0$, $a_2 > 0$, and $A_{11} < 0$, $A_{22} < 0$, but $A_{12} > 0$, $A_{21} > 0$, and $A_{1I} > 0$ and $A_{2I} > 0$. Also, $\partial \log a_{m1} / \partial \log p_1 > 0$ and $\partial \log a_{m1} / \partial \log p_2 > 0$, but $\partial \log a_{m1} / \partial \log p_I < 0$. It should also be noted that $A_{11} + A_{12} + A_{1I} = 0$ and $A_{21} + A_{22} + A_{2I} = 0$ (from the homogeneity property of input coefficients). Similarly, it is known that

$$\frac{\partial \log a_{m1}}{\partial \log p_I} = -\frac{\partial \log a_{m1}}{\partial \log p_1} - \frac{\partial \log a_{m1}}{\partial \log p_2}$$

Making use of these expressions the denominator of $d \log p_I / d \log K$ becomes:

$$\left(A_{21} - A_{11}\right)(a_1 - 1) + \left(A_{22} - A_{12}\right)(a_2 - 1) + \left[\frac{\partial \log a_{m1}}{\partial \log p_1}(a_1 - 1) + \frac{\partial \log a_{m1}}{\partial \log p_2}(a_2 - 1)\right] |b|$$

Furthermore, it can easily be shown that $|\alpha| > 0$ implies that $a_1 < 0$, $a_2 > 1$, and also $|b| > 0$.

For the Heckscher-Ohlin theorem to remain unscathed, clearly the denominator would have to be negative. If there are no complementarities between factors, the expression $(A_{21} - A_{11})(a_1 - 1) + (A_{22} - A_{12}) \cdot (a_2 - 1)$ will be negative.[2] But unfortunately the sign of

$$(5) \quad \left[\frac{\partial \log a_{m1}}{\partial \log p_1}(a_1 - 1) + \frac{\partial \log a_{m1}}{\partial \log p_2}(a_2 - 1)\right]$$

is unknown. It therefore follows that the Heckscher-Ohlin theorem breaks down. As a considerable amount of trade takes place in intermediate products, this seems to be a result of some importance. The Heckscher-Ohlin theorem is inadequate in explaining trading patterns when pure traded intermediate products are allowed for. There are the following special cases in which the Heckscher-Ohlin theorem remains valid:

1) when intermediate input coefficients are fixed

2) when $\dfrac{d \log a_{m1}}{d \log p_I} = \dfrac{\partial \log a_{m1}}{\partial \log p_I}$

It may easily be shown that if condition 2) is fulfilled, expression (5) vanishes. The economic interpretation of the second set of special conditions is quite straightforward. The Heckscher-Ohlin theorem remains valid if the total elasticity of the intermediate input coefficient (allowing for variations in the prices of original factors of production) is equal to the partial elasticity of the intermediate input coefficient (keeping p_1 and p_2 fixed) with respect to the price of the intermediate product. Briefly, the condition under 2) can be interpreted to entail that substitution between original factors of production and the intermediate input is unbiased.[3]

Did the 1968 Surcharge Really Work?

By William L. Springer*

In a recent article, Arthur Okun (1971) has examined the effects on aggregate consumer expenditures of the recent temporary income tax surcharge (officially known as the Revenue and Expenditure Act of 1968), using the consumption sector equations from four prominent macroeconomic models (Data Resources, Inc. (*DRI*), Wharton, Office of Business Economics, and Michigan). On the basis of his analysis, Okun concluded that "the evidence of the surcharge period as interpreted by four econometric models indicates that the surcharge curbed consumption nearly as much as was expected, and that any shortcomings in its effectiveness have no evident connection to the permanent income hypothesis" (p. 198). Moreover, "the evidence . . . provides further confirmation of the general efficacy and continued desirability of flexible changes in personal income tax rates—upward or downward, permanent or temporary" (p. 200). Thus, in spite of its admitted failure to halt the inflationary surge of the late 1960's, Okun claims that the surcharge accomplished what it was designed to do—namely, to reduce consumer expenditures. The persistence of inflation would have to be explained by (perhaps) offsetting increases in other components of aggregate demand (for example, state and local government expenditures), an overexpansive monetary and credit policy, inflationary expectations, or cost-push pressures from big business and labor.[1]

Viewed against the widely accepted "permanent income" and "life cycle" hypotheses of consumer behavior which predict small changes in consumption in response to temporary changes in income, Okun's results are somewhat puzzling. As Robert Eisner (1969) has pointed out, " . . . the tax surcharge should never, on basic theoretical grounds, have been considered an effective anti-inflationary device. . . . The basic economic error of those who saw in the 10 percent income tax surcharge an adequate measure against inflation may be charged to failure to take into account the implications of the permanent income hypothesis . . . " (p. 898). The question, then, is how can Okun's apparent finding that the surtax "worked" be reconciled with the prior expectation that it would not work because of its temporary nature.

As part of a more extended study of windfall income, temporary income taxes, and consumer behavior, I have performed essentially the same kind of error analysis over the surcharge period as Okun did. However, using more suitable estimation and simulation procedures, along with a somewhat different set of consumption equations, I arrived at exactly the opposite conclusions. In particular, it was found

---

* Senior economist, Data Resources, Inc. This paper is based on two chapters of my unpublished doctoral dissertation. I wish to thank Alan Blinder and William Branson of Princeton University and an anonymous referee for extremely helpful comments and suggestions, but I alone assume responsibility for any remaining errors.

[1] Using simple Keynesian macro models, Alan Blinder has investigated the conditions under which an increase in income taxes might actually lead to *higher* prices (via the indirect route of workers demanding a constant after-tax wage). Except in a Monetarist model, the effect of such a tax change on prices is always ambiguous. However, Blinder concludes that under reasonable assumptions concerning values for the marginal tax rate, the tax multiplier, labor's share, and the supply and demand elasticities for labor, income tax increases will have the desired deflationary impact.

that the 1968 surcharge did *not* lead to a significant reduction in consumption expenditures. This result is consistent not only with generally accepted theory, but also with the well-known fact that a significant drop in the savings rate occurred in late 1968 and persisted throughout 1969. The finding that consumer expenditures were not effectively curtailed by the tax also helps explain why inflation continued unabated after 1968.

It therefore appears that this episode of fiscal policy does not in fact provide any evidence whatsoever that temporary income taxes will have a discernible impact on consumption. On the contrary, the data seem to confirm what theory predicts and what casual empiricism at the time suggested. These findings should be of particular interest to government fiscal policy makers who, within a recent period of about four months, proposed first a temporary 5 percent income tax surcharge and then a one-time rebate on 1974 taxes. Such small and temporary measures simply cannot be expected to have a significant effect on total aggregate demand.

Section I lays some rudimentary theoretical groundwork, Section II discusses the nature of the experiment, Section III describes the data, Section IV presents the empirical results, and Section V summarizes the main conclusions.

I. Theoretical Considerations

Although Okun's approach suffers from its lack of grounding in a well-developed theoretical framework, the intention here is not to present a full-blown treatment of windfalls, but rather to challenge Okun on his own ground, i.e., by performing experiments similar to those reported in his paper.[2] Nevertheless, since my equations do follow from specific theoretical models, it is necessary to outline briefly their derivation.

The first point to be noted is that my equations split consumer expenditures according to the economist's rather than the national income accountant's definitions. That is, "consumption" is here defined to include depreciation and imputed interest on durables, as well as expenditures on nondurables and services. This might seem to muddy the waters a bit, since Okun's equations are all based on National Income Accounts (*NIA*) concepts. Moreover, from a policymaker's point of view, the ultimate concern is with *expenditures* rather than the theoretically more appealing concept of consumption. However, the difference turns out to be more apparent than real, since expenditures on nondurables and services constitute roughly 80 percent of total consumption, and the "use value" on durables is essentially a trend. Thus, movements in consumption will be dominated by movements in expenditures on nondurables and services. As for consumer durables, the model can be developed either in terms of net or gross expenditures. The latter concept was chosen for this study and is also the one used in Okun's forecasting equations.

A. *Consumption*

The consumption equation follows from the straightforward maximization of a well-behaved, additively separable, intertemporal utility function, subject to the budget constraint that discounted consumption plus bequests must equal the sum of discounted future disposable income.[3] Assuming the utility function to be homogeneous of some positive degree, the maximization process yields an optimal consumption path which is a proportional function of lifetime income, where the proportionality factor depends on an individual's age, his subjective rate of time preference (tastes), and the market rate of interest.

---

[2] A theory of windfalls is developed in my dissertation, together with a discussion of its application to the question of flexible tax policy.

[3] In most studies of the consumption function, the budget constraint is expressed in terms of initial assets and *labor* income. Because of the difficulty in obtaining an accurate and consistent series for labor income, lifetime resources are here defined as the sum of the discounted *disposable* income stream. Since this concept includes income from property, net worth should not appear as an explanatory variable in the consumption function.

$$(1)\qquad con^*_{it} = k_i\left[\sum_{t=T}^{L} \frac{yd^e_{it}}{(1+rr_t)^{t-T+1}}\right]$$

where

con^*_{it} = desired consumption of individual i in time period t
yd^e_{it} = disposable income expected (with certainty) in time period t
rr_t = real market rate of interest
T = present age of individual i
L = life span of individual i
k_i = proportionality factor
= k (age, tastes, rate of interest)

In the spirit of Franco Modigliani and his collaborators (1954, 1963) and Milton Friedman, lifetime disposable income is converted into a yearly income flow—"annual expected disposable income" ($\overline{yd}^e_{it}$)—defined as the implicit (constant) annuitized income stream. Thus,

$$(2)\qquad \overline{yd}^e_{it} = \frac{\displaystyle\sum_{t=T}^{L} \frac{yd^e_{it}}{(1+rr_t)^{t-T+1}}}{\displaystyle\sum_{t=T}^{L} \frac{1}{(1+rr_t)^{t-T+1}}}$$

$$(3)\qquad con^*_{it} = \alpha_i(\overline{yd}^e_{it})$$

where[4]

$$\alpha_i \equiv k_i \sum_{t=T}^{L} \frac{1}{(1+rr_t)^{t-T+1}}$$

Under the assumption of a constant proportionality factor α for each age group, a stable population distribution, and a stationary income distribution when (3) is aggregated over the entire population, the corresponding macro coefficient will be time invariant. Whether it differs at a given point in time from the simple average of α_i depends on the covariance between these micro slopes and the income distribution parameters. If, for example, the marginal propensity to consume (*MPC*) declines with income as many have claimed, the estimated macro coefficient will exhibit negative "aggregation bias," i.e., the macro *MPC* will understate the unweighted mean of the micro *MPC*s. But this aggregation bias (if it exists) at least will not vary from period to period under the stated assumptions.

Aggregated desired consumption in each period is now:

$$(4)\qquad CON^*_t = \beta\overline{YD}^e_t$$

where

CON^*_t = aggregate desired consumption
$\overline{YD}^e_t$ = aggregate annual expected disposable income
$\beta = \beta$ (age, tastes, rate of interest)

Aggregate *measured* consumption is the sum of desired and transitory consumption.

$$(5)\qquad CON_t = CON^*_t + CON^r_t$$

where

CON_t = measured consumption
CON^*_t = desired or permanent consumption
CON^r_t = residual or transitory consumption

If we depart from the strict Friedman hypothesis of zero correlation between transitory income and consumption, and allow for some expansion and contraction of consumption (for example, of nonessential items) in response to transitory income changes,[5] then aggregate transitory consumption is defined as:

---

[4] Under the assumptions of an infinite lifetime and a constant rate of interest, $\overline{yd}^e_{it}$ becomes identical to Friedman's "permanent income."

[5] Because the "consumption" variable used here is constructed using *NIA* concepts, it is impossible to ex-

$$CON^T_t = \gamma YT_t \tag{6}$$

where YT_t = aggregate transitory income
$\gamma = MPC$ out of transitory income

This yields for measured consumption:

$$CON_t = \beta \overline{YD}^e_t + \gamma YT_t \tag{7}$$

Using the identity that measured disposable income is the sum of annual expected income and transitory income ($YD_t = \overline{YD}^e_t + YT_t$), the expression for aggregate measured consumption becomes:

$$CON_t = \gamma YD_t + (\beta - \gamma)\overline{YD}^e_t \tag{8}$$

It will be recalled that β is a function of age, tastes, and the rate of interest. While it is probably not too far from the mark to assume that tastes and the age distribution have been relatively stable over the last twenty years, it is less defensible to make such an assumption with respect to the interest rate. In the early studies of the consumption function, the interest rate was assumed to be zero or constant in time. At the time these articles appeared, rates of interest showed relatively little fluctuation, so that such assumptions may have been legitimate. However, in recent years, both real and nominal rates have varied significantly, so that the potential impact on consumption can no longer be safely ignored.

In principle, β is a function of current and future rates of interest. However, the simplifying assumption will be made that it is a linear function of the current rate only, i.e., that

$$\beta = b_0 + b_1 rr_t \tag{9}$$

Substituting this into (8), we have:

$$CON_t = \gamma YD_t + (b_0 + b_1 rr_t - \gamma)\overline{YD}^e_t \tag{10}$$

Or, simplifying the notation, the final estimating equation for consumption is:

$$CON_t = B_{11} YD_t + B_{12}\overline{YD}^e_t + B_{13}(rr_t \cdot \overline{YD}^e_t) + u_t \tag{11}$$

where u_t is the stochastic error term.

B. *Consumer Durables*

The model of investment in consumer durables used in this study draws heavily on the work of Thomas Juster and Paul Wachtel (1972a,b) and Saul Hymans. Basically, their aim is to supplement the traditional "objective" stock-adjustment model of durables expenditures with "anticipatory" variables designed to measure consumer sentiment. They find that these sentiment indexes do indeed improve the explanatory power of durables equations. Without going through the theoretical derivation, the estimating equation for gross expenditures on consumer durables looks as follows:

$$\begin{aligned} CD_t = {} & B_{21} + B_{22} YD_t + B_{23}\overline{YD}^e_t \\ & + B_{24}\left(\frac{PCD}{PNS}\right)_t + B_{25} rr_t \\ & + B_{26} KCD_{t-1} + B_{27} UN_t \\ & + B_{28} ASTRIKE + B_{29} NCD_{t-1} \\ & + B_{210} UN_{t-1} + B_{211} FMOOD_t + v_t \end{aligned} \tag{12}$$

where CD_t = gross expenditures on consumer durables
NCD_t = net expenditures on consumer durables
KCD_t = net stock of consumer durables
PCD_t = implicit deflator for durables
PNS_t = implicit deflator for nondurables and services
YD_t = current disposable income
$\overline{YD}^e_t$ = average annual expected income
rr_t = real rate of interest

---

clude discretionary expenditure terms entirely. Thus, while in principle it is possible to imagine some subset of total consumption expenditures which is totally uncorrelated with transitory income, in practice this is difficult to attain because of the way the data are actually measured and reported.

UN_t = aggregate unemployment rate

$ASTRIKE_t$ = automobile strike dummy: +1 in 59-IV, 64-IV, 67-IV and 70-IV; and −1 in 60-I, 65-I, 68-I and 71-I

$FMOOD_t$ = "filtered" version of the Michigan Survey Research Center's Index of Consumer Sentiment.[6]

II. The Nature of the Experiment

Okun's experiment consisted of measuring the prediction errors of the consumption sector equations under two different assumptions. According to the "full-effect" hypothesis, the surtax was treated like any other change in disposable income, so that consumption over the period would be best explained by actual measured disposable income. The alternative "zero-effect" view holds that consumption was closer to what would have been predicted had there been no surcharge at all. That is, this hypothesis essentially says that consumers behaved as if they had lost no income at all. Thus, in this case, the relevant explanatory variable is disposable income, less the (negative) surtax, i.e., the amount of the tax is added back. Our prior expectation is that actual consumption should fall somewhere in the interval bounded by predictions based on the two extreme views. If the residuals have a positive bias on the full-effect view and no bias on the zero-effect view, the latter hypothesis would be confirmed. But if they have a negative bias on the zero-effect view and are unbiased on the full-effect view, the full-effect hypothesis would be validated.[7]

The prediction errors of my equations will be compared over the entire period 1968-III to 1971-IV and for the subperiods, 1968-III to 1969-II, 1968-III to 1970-II, and 1970-III to 1971-IV. There are two reasons for making comparisons over these particular intervals. In the first place, from the point of view of the effectiveness of stabilization policy, the major concern is with what happens in the first and second years following imposition of the surcharge. For if temporary taxes and transfers are seriously being considered as a means of stabilizing aggregate demand, then it is certainly to be hoped that they will yield significant results within at least two years, and preferably within one. It therefore seemed appropriate to examine the residuals over shorter periods of time following initiation of the tax. (Okun looked only at the nine-quarter interval, 1968-III to 1970-III.)

A second and more practical reason for

---

[6] See Juster and Wachtel (1972b) for a description of this variable.

[7] While Okun discusses the permanent income arguments against effectiveness of the surtax and even claims to have refuted them with his results, his experiment does not in fact provide a direct test of the theory. In the first place, by using an equation estimated with actual disposable income and by adjusting only the current income term, the experiment *assumes* that the surcharge was treated like any other change in disposable income. But this is the central point at issue. Secondly, validation of the full-effect view does not necessarily imply contradiction of the permanent income hypothesis, for the simple reason that nearly all the equations used by Okun implicitly assume this theory by incorporating lagged values of consumption and income. Moreover, most of his equations carry very small coefficients on the current income term—a result which is predicted by the permanent income hypothesis and which suggests immediately that temporary changes in income will have a small impact on consumption. And finally, the zero-effect view in effect assumes that the estimated historical relationship between consumer expenditures and income was somehow altered during the surcharge period, so that consumers behaved *as if* they had more income than they really did. Thus, the amount of the tax is arbitrarily added back to disposable income to force the equation to predict a higher level of consumption. But the permanent income theorists do not need to assume that the surtax did not happen in order to obtain their prediction of ineffectiveness. Their point is simply that because the income loss was temporary and because such changes in income carry a small *MPC*, consumption was little affected. A direct test of the permanent income hypothesis requires an examination of the distributed lag behavior of a separately entered surcharge variable and estimation of the propensity to consume out of it. Such a test is performed in the author's dissertation.

splitting out the last six quarters and treating them separately is that there seems to have been some factor, not fully accounted for in the specified equation, which caused consumption to be unusually *low* in 1971. It seems doubtful that this was related to the surcharge, and even if it was, it does not say much for the short-run effectiveness of the measure. Moreover, this analysis is really concerned with first-round effects of the tax, and these were over by 1970-IV. Thus, since 1971 seems to confuse the issue somewhat, results which exclude this period will be presented.

Three measures of error are used in analyzing the residuals: mean absolute error (MAE), root mean squared error ($RMSE$), and the mean error (ME). Note that the residual $\hat{e}$ used in the calculation of these measures is the nonautocorrelated error term.[8]

In calculating predicted values of the expenditure variables, lagged residuals are generated by using lagged *predicted* values of the dependent variables. This "dynamic" procedure is generally considered to be the acid test of the predictive accuracy of an equation containing the lagged value of the dependent variable and/or an autocorrelated error term. If instead, lagged residuals are generated using *actual* lagged values of the dependent variable, then as stated by Okun: "predictions based on an incorrect theoretical view of consumption are mechanically corrected and approach the predictions based on the valid analytical view" (1971, p. 182). On the other hand, under the dynamic method, if predictions are consistently wrong in one direction or another, they will cumulate and become very obvious. An equation which predicts well when errors are fed back into it dynamically can with more accuracy be said to reflect the valid analytical view.

III. Data and Estimation Methods

The data used in estimating equations (11) and (12) are expressed in billions of 1958 dollars seasonally adjusted at annual rates, and are derived from the standard National Income Accounts tables published by the Department of Commerce. The sample period runs from the first quarter of 1955 to the fourth quarter of 1971.

Consumption (CON) is defined as the sum of expenditures on nondurable goods and services (CNS), depreciation on the stock of durables (WCD), and the implicit stream of rental services on the existing stock of durables (YCD).[9] Since consumption includes the implicit yield on durables, YCD must be added to measured disposable income in order to maintain the accounting identity. Data on the estimated dollar amounts of tax accruals yielded by the surcharge were supplied by the Department of Commerce and may be found in Okun (1971).[10] In all cases, the expected income and interest rate interaction terms have been made consistent with the definition of current disposable income.

---

[8] Ideally, confidence intervals should also be constructed around the prediction errors and significance tests performed thereon. This is not done because the additional computation involved was not readily available. Furthermore, it is highly unlikely that such tests would alter the nature of the results derived from the simple error measures used here.

[9] See William Poole for a convenient exposition of the method by which CON is constructed.

[10] Albert Ando and E. Cary Brown discuss the question as to whether consumer expenditures in the short run can best be explained by disposable income with taxes subtracted on a liability basis, or an accrual basis (the latter concept being the one used in the National Income Accounts). Under normal assumptions, a utility optimum is achieved with a smooth consumption path, so that we would expect rational individuals to adjust their consumption patterns to the smooth trend of tax liabilities rather than to tax accruals, which *may* be more volatile. Actually, except in unusual circumstances, accruals and liabilities are likely to move closely together and therefore should perform equally well in explaining consumer expenditures. It is only when they exhibit sharply differing movements that we must be concerned about which concept to use in a consumption equation. There is no evidence that such a divergence occurred over the surcharge period.

Annual expected income is not observable and so must be approximated in some manner. The most common way of doing this is to assume that expected disposable income is generated according to the adaptive expectations mechanism suggested by Marc Nerlove. Thus,

$$(13)\quad \begin{aligned}\overline{YD}^e_t &= \overline{YD}^e_{t-1}(1+g) \\ &\quad + h(YD_{t-1} - \overline{YD}^e_{t-1}) \\ &= hYD_{t-1} + (1 - h + g)\overline{YD}^e_{t-1}\end{aligned}$$

where g is a quarterly growth trend factor and h is the coefficient of expectation or adjustment, which takes on a value between zero and one. The initial value for $\overline{YD}^e_{t-1}$ (fourth quarter of 1948) was calculated as the simple average of disposable income from 1948-II through 1949-II, or \$232.8 billion. The growth rate of income (.0094) was the estimated slope in a regression of the *log* of disposable income on a constant and time. A value of .1 for h was chosen as that value between .1 and .2 which minimized the sum of squared residuals in a series of regressions using equation (11). The same procedure was followed in calculating $\overline{YD1}^e$, average expected disposable income, less the (negative) surcharge.

The nominal interest rate rn is a weighted average of rates on savings and loan shares, mutual savings bank deposits, and time deposits in commercial banks with weights being determined by the share of each asset in the portfolio of savings deposits in the household Flow of Funds Accounts as of the end of 1971. The nominal rate of interest rn was converted to a real rate of interest rr by subtracting the expected rate of inflation PE. Both rn and rr are expressed in percent.

PE was calculated by assuming an adaptive expectations mechanism for price formation.

$$(14)\quad PE_t = PE_{t-1} + \bar{h}(dP_t - PE_{t-1})$$

where PE_t = expected rate of price change (percent)

dP_t = actual percentage rate of price change $= ((P_t - P_{t-1})/P_{t-1}) \times 100$

$\bar{h}$ = coefficient of expectation, $0 < \bar{h} < 1$

By recursive substitution, (14) may be written as:

$$(15)\quad PE_t = \bar{h}\sum_{i=0}^{\infty}(1-\bar{h})^i dP_{t-i}$$

Thus, the current expected rate of inflation may be expressed as an infinite geometrically distributed lag on actual past rates of inflation. Rather than estimate the lag structure directly, a set of assumed weights was taken from Robert J. Gordon who estimates an interest rate equation with an Almon polynomial distributed lag on past price changes. It was arbitrarily decided to use the weights for the first three years only (12 quarters), and to normalize them to sum to one.

The price variable used in this work is the implicit GNP deflator. This was chosen to avoid both the possible spurious bias caused by using the consumption deflator in consumption equations, and the apparent upward bias of the fixed-weight Consumer Price Index as noted by Gordon, p. 111.

Although contemporaneous correlation undoubtedly exists between the regressors and the disturbance, so that least squares estimates will be biased and inconsistent, the results reported here have not accounted for the simultaneous equation problem. All equations were estimated by ordinary least squares, using the Cochrane-Orcutt iterative technique to correct for autocorrelated residuals. Ray Fair (1971) has reported that in estimating equations with aggregate quarterly data, it is apparently more important to remove autocorrelation than simultaneity. Two-stage least squares estimates tend to differ little from their ordinary least squares counterparts, whereas the Cochrane-Orcutt transformation often yields quite different coefficient estimates. Some experimentation by this author using a consistent estimation procedure suggested by Fair (1970) corroborated his findings, so that failure to use two-stage least squares estimates has essentially no bearing on the results.[11]

IV. Empirical Results

A. *Consumption*

The equations estimated under the full- and zero-effect views of the surcharge are given below in (16) and (17).

Full-Effect

$$(16)\quad CON_t = \underset{(0.5)}{2.74} + \underset{(4.2)}{0.26}YD_t + \underset{(10.1)}{0.65}\overline{YD}_t^e + \underset{(1.9)}{0.004}(rr_t \cdot \overline{YD}_t^e)$$

$$R^2 = .9996;\quad SE = 1.4664;\quad DW = 2.5270;\quad \hat{\rho} = \underset{(12.6)}{0.84}$$

Zero-Effect

$$(17)\quad CON_t = \underset{(1.0)}{2.84} + \underset{(6.7)}{0.34}YD1_t + \underset{(10.7)}{0.56}\overline{YD1}_t^e + \underset{(4.6)}{0.005}(rr_t \cdot \overline{YD1}_t^e)$$

$$R^2 = .9996;\quad SE = 1.3936;\quad DW = 2.4336;\quad \hat{\rho} = \underset{(7.5)}{0.67}$$

In these equations, YD refers to actual disposable income, while $YD1$ refers to disposable income less the (negative) surcharge. These two variables are identical except for the nine quarters, 1968-III through 1970-III. The t-statistics are shown in parentheses below the coefficient estimates.

A cursory look at the income coefficients in both (16) and (17) should suggest immediately that income taxes of any kind will not be a very effective weapon of stabilization policy. The relatively small estimated coefficients on current income, together with the small coefficient of expectation (.1) on expected income, indicate that even a permanent alteration in income taxes would yield only small short-run changes in consumption, and that the lag between implementation and full impact would be long. And if the tax change were temporary (even assuming it is treated like an ordinary change in disposable income), the long-run impact on consumption would ultimately be much smaller as well. The coefficient on the interest rate interaction term is positive, indicating that the income effect dominates the substitution and asset effects of an interest rate change.

Although the differences in the statistical properties of the two equations are not large, the zero-effect equation (17) is clearly superior to the full-effect equation (16). In (17) the standard error and $\hat{\rho}$ are both smaller, the Durbin-Watson statistic is closer to 2, and the parameters are uniformly more significant. More persuasive evidence of the superiority of the zero-effect view is provided by an examination of the predictive power of the two equations. Tables 1 and 2 present the actual and dynamic residuals for both equations, and the summary measures of their prediction errors over various time periods following institution of the surcharge.

The error pattern indicates that while the percentage errors are quite small, both equations are generally underpredicting consumption in the first eight quarters. However, this is much more pronounced in the case of the full-effect view, where the *RMSE* over this interval for equation (16) is roughly twice that for equation (17).[12]

---

[11] See the author's dissertation for a more extensive discussion of the data and estimation methods used.

[12] Note that the direction of error is just the opposite

68-III to 71-IV	2.132	2.478	0.4314

[a] $MAE = \frac{1}{n}\sum_{t=1}^{n} |\hat{e}_t|$

[b] $RMSE = \sqrt{\frac{1}{n}\sum_{t=1}^{n} (\hat{e}_t)^2}$

[c] $ME = \frac{1}{n}\sum_{t=1}^{n} \hat{e}_t$

Over the last six quarters (1970-III to 1971-IV), both equations are overpredicting, but yield residuals of roughly the same size. For the period as a whole (1968-III to 1971-IV), the zero-effect equation yields significantly smaller errors than the full-effect equation, with the difference being most pronounced over the first eight quarters.

Although there is relatively little bias in the residuals over the entire fourteen quarters on the zero-effect view, it is somewhat puzzling that consumption was slightly higher even than predicted by the zero-effect view during the first eight quarters—the period when the surcharge was supposed to be having its major impact—and lower even than predicted by the full-effect view in the last four quarters. It is highly unlikely that the tax *stimulated* consumption while it was in effect and then finally began to *reduce* spending after it was removed. And even if such an hypothesis were not implausible on basic theoretical grounds, it would imply extremely long lags in effectiveness which would render the tax useless as a short-run stabilization device. The fact is that even under the preferred zero-effect view the equation as specified does not track consumption very well in 1971, when something else seems to have been holding down spending. An attempt was made to identify the cause of the unusually low levels of consumption in 1971, but a completely satisfactory answer was not found.[13]

Thus, having performed Okun's experiment using a simple consumption function derived precisely from standard economic theory, it must be concluded that actual consumption was closer to the levels predicted by the zero-effect view than to those predicted by the full-effect view. Contrary to Okun's findings, consumption appears to have been unaffected by the surcharge, as consumers did in fact discount the temporary tax.

---

from that reported by Okun. Except for the *DRI* equations, his models consistently *over*predict consumption of nondurables and services on either view by a disturbingly large margin.

[13] See the author's dissertation for a discussion of these tests.

B. *Consumer Durables*

While it appears that *consumption* was little affected by the income tax surcharge, there is no presumption one way or the other as to the effect on total consumer *expenditures*. The permanent income/life-cycle theory says only that temporary changes in income will be reflected in savings flows, defined to include personal saving (National Income Accounts basis) and net expenditures on durables. Clearly, which component of saving is primarily affected by a temporary tax determines what the ultimate impact on total expenditures will be. Thus, if the saving takes the form of changes in the stock of durable goods, instead of financial assets, then although *consumption* may be unaffected by the tax, the measure must still be considered a successful instrument of stabilization policy since it has caused the desired change in total consumer expenditures.

This is a point often missed by those who have criticized the theoretical justification for the 1968 income tax surcharge. These critics make the valid point that a temporary change in income taxes will probably have a miniscule effect on current consumption, and then conclude that such taxes are a useless tool of stabilization policy. However, the second conclusion does not necessarily follow from the first because they relate to two different concepts—consumption and consumer expenditures. It is the latter concept which is most relevant in the context of economic stabilization, and it is therefore necessary to look into the question of the allocation of temporary income between real and financial assets. On a priori grounds, there is little justification for believing that this allocation occurs in any particular fashion; it would seem to be a purely empirical matter. It is a great irony that it could turn out that the permanent income theorists, who have denigrated the usefulness of temporary income taxes, and the proponents of an active and flexible fiscal policy could both be right!

The durables equation (12) was estimated over the sample period (55-I to 71-IV) using the two definitions of disposable income, and dynamic simulations were run over the surcharge period. In these simulations, only the lagged error term is fed through dynamically. The equations, their residuals, and the summary error measures are shown below.

Full-Effect

$$(18)\quad CD_t = \underset{(0.4)}{8.69} + \underset{(2.3)}{0.08}YD_t + \underset{(0.6)}{0.05}\overline{YD}^e_t - \underset{(1.1)}{21.2}\left(\frac{PCD}{PNS}\right)_t - \underset{(1.5)}{0.66}rr_t + \underset{(0.7)}{0.07}KCD_{t-1} - \underset{(0.6)}{0.35}UN_t - \underset{(6.3)}{3.43}ASTRIKE + \underset{(7.8)}{0.73}NCD_{t-1} + \underset{(1.4)}{0.28}UN_{t-1} + \underset{(4.4)}{0.45}FMOOD_t$$

$R^2 = .9955$; $SE = 1.31203$; $DW = 2.1129$; $\hat{\rho} = -\underset{(2.7)}{0.32}$

Zero-Effect

$$(19)\quad CD_t = \underset{(0.4)}{8.59} + \underset{(3.0)}{0.13}YD1_t - \underset{(0.4)}{0.04}\overline{YD1}^e_t - \underset{(0.8)}{17.08}\left(\frac{PCD}{PNS}\right) - \underset{(0.8)}{0.44}rr_t + \underset{(1.0)}{0.12}KCD_{t-1} + \underset{(0.1)}{0.07}UN_t - \underset{(6.3)}{3.32}ASTRIKE + \underset{(6.3)}{0.63}NCD_{t-1} - \underset{(0.2)}{0.14}UN_{t-1} + \underset{(4.6)}{0.48}FMOOD_t$$

$R^2 = .9957$; $SE = 1.28066$; $DW = 2.09$; $\hat{\rho} = -\underset{(2.1)}{0.24}$

An examination of the equations and their residuals indicates again that the zero-effect view dominates the full-effect view, although the difference is not nearly so striking as in the case of consumption. This is due to the fact that the coefficients on the income terms are quite small, so that adjusting income by a relatively small amount will make very little difference in the predicted value of spending on durables. The summary statistics are all better for equation (19) than for (18) and the residuals are smaller. However, it will be noted that the mean error over the first two years, as well as over the entire period, is uniformly positive under either view. This suggests that there is some other (unspecified) explanatory variable at work causing durables expenditures to be higher than expected. Therefore, the best that can be said about the surcharge is that it had no effect on durables spending. Evidently, the temporary drop in income *was* reflected in financial saving (see Table 5).

The results reported here for durables are really not very different from Okun's. He does not use total durables equations nor show us summary results for the total, but rather breaks it up into "autos" and "other durables." While he claims that his results from the other durables equation confirm the full-effect hypothesis, a closer examination of his own residuals and calculated *RMSE*s suggests that an hypothesis of 50 percent effectiveness would be closer to the mark. As for autos, he essentially ignores these equations, because the residuals imply that the surcharge led to significantly ***higher*** spending on cars, a finding which is completely at odds with expectations. Had he combined his results for both categories of durables, Okun would have been forced to the conclusion

TABLE 5—SAVINGS RATE

$$(\%) = 100 \times \frac{\text{personal saving, } NIA \text{ basis}}{\text{measured disposal income}}$$

Quarter	1967	1968	1969	1970	1971
I	7.4	7.2	5.3	6.9	8.2

that the surtax had no appreciable impact on this category of expenditures. Thus, his assertion that the surtax represented a successful application of flexible fiscal policy ultimately must hinge on his results for nondurables and services, which appear to differ markedly from my findings. It is to this discrepancy that I now turn.

C. *Why the Contradictory Results?*

1. In the first place, Okun's conclusion that the surcharge worked never was consistent with the incontrovertible fact that the saving rate took a sharp dip in late 1968 and throughout 1969 (see Table 5). It seems difficult to explain this other than by concluding that consumers maintained their spending patterns in the face of the surtax and financed this behavior by lowering their rate of saving.

2. Others have already questioned the validity of the conclusions Okun draws from his own analysis. Okun's assertion that the surcharge was 63 to 88 percent effective was obtained by imposing certain arbitrary constraints on his results. A more judicious interpretation of his findings would place the degree of effectiveness at something less than 50 percent.[14] Taken along with Okun's own statement that only one-half of the drop in disposable income was expected to be reflected in consumer spending (1971, p. 194), we are left with a surcharge impact of at best one-fourth that expected from a permanent change in taxes! Thus, Eisner's hypothesis of an *MPC* of .1 out of temporary income tax charges may not be as "wide of the mark" as Blinder and Solow maintain (p. 109).

3. My results are not strictly comparable to Okun's because the "consumption" variable includes depreciation and the implicit return on durables, along with expenditures on nondurables and services. Okun's equations, on the other hand, disaggregate consumer expenditures along the lines of the National Income Accounts. Therefore, in order to achieve stricter comparability the experiment was performed with an equation (using the same basic specification) in which nondurables and services was the dependent variable. This test (reported in my dissertation) merely confirmed the earlier finding that the surtax was ineffective in curbing consumption, regardless of whether or not it is defined to include the "use value" of durables. Such a result was to be expected since expenditures on nondurables and services constitute roughly 80 percent of the total value of consumption, while the use value on durables is essentially a trend which grows with the stock of real assets.

4. A possible source of bias in Okun's results may lie in the fact that the models which he used for simulating both zero- and full-effect views were all *estimated* using the full-effect concept of disposable income, (i.e., actual measured income). Thus, it is possible that his conclusions are thereby biased toward the full-effect view.[15] This question was explored by fitting my full-effect equation for consumption (16) to the data, but then performing the dynamic simulation using the zero-effect definition of income (which is how Okun tested the zero-effect view). Conversely, the zero-effect equation was simulated using full-effect income.

The results of this experiment (see the author for the details) pointed even more strongly to the superiority of the zero-effect view of the surcharge. The *RMSE* was considerably smaller for the zero-effect hypothesis (1.369) over the surcharge period than for the full-effect view (5.087).[16] Thus, when equations are estimated with one income concept and used to test the hypothesis concerning the other concept, the predicted values are not biased toward the income concept used in the estimation process. In this case, mixing the two definitions of income serves only to corroborate further the view that the surcharge had no appreciable impact on consumption. On a priori grounds, of course, it is preferable to test the alternative hypotheses by simulating equations which have been fitted using the corresponding definitions of income, as was done here.

---

[14] On this point, see Blinder and Robert Solow, William Branson, and comments by Eisner in Okun (1971).

[15] Okun (1971, p. 184) admits the possibility of such bias in his results, but does not pursue the matter.

[16] Such a result could have been anticipated from an

5. Two other possible explanations of the contradictory results were also explored, and the conclusions will be summarized here (see the author for further details). In the four forecasting models used by Okun, the independent variables consisted of some combination of income, lagged income, and lagged expenditure, plus assorted other *ad hoc* variables. None of these equations uses a real rate of interest, a variable which is grounded in theory and which does appear in my equations with considerable explanatory power. It therefore seemed appropriate to ask whether it was this interest rate variable which was making the zero-effect view come out better. However, when the experiment was performed with equations which excluded the interaction term, the basic finding of ineffectiveness of the surtax was not changed.

Secondly, a number of Okun's equations suffer from the problem of autocorrelated errors. Furthermore, it is likely that the autocorrelation in most cases is actually worse than it appears because of the presence of lagged dependent variables in many of the equations.[17] Since it has been found that estimated coefficients often change significantly when using ordinary least squares without the Cochrane-Orcutt transformation, I performed the experiment with an equation which did not employ this correction procedure. Again, however, the zero-effect view yielded smaller residuals over the surcharge period than did the full-effect view.

6. Having examined individually three possible sources of the discrepancy between Okun's and my results and failed to come up with a satisfactory explanation, the mystery was finally resolved by combining them. Thus, using an equation estimated by ordinary least squares, with the full-effect definition of income, and without an interest rate term, the equation was simulated over the fourteen-quarter period, 1968-III to 1971-IV, under the two alternative definitions of income. This is as close to Okun's procedure that I can get without completely changing my equations. The simulations now, of course, are static rather than dynamic. The results are shown below.

Full-Effect

$$CON_t = \underset{(0.02)}{-\,0.048} + \underset{(10.1)}{0.47\,YD_t} + \underset{(9.0)}{0.44\,\overline{YD}_t^{\,e}} \tag{20}$$

$R^2 = .9984$; $SE = 2.8737$; $DW = .3351$; (Ordinary Least Squares)

Comparing the error measures in Tables 6 and 7, except for the first four quarters following enactment of the surtax, the full-effect view outperforms the zero-effect view, in the sense that the average error is smaller. The period 1968-III to 1970-II is almost identical to Okun's simulation interval, and the *RMSE* is smaller for the

---

examination of the estimated coefficients on current income in equations (16) and (17).

[17] In general, the Durbin-Watson test is not applicable in situations where lagged values of the dependent variable are among the explanatory variables, and is biased toward two in such a case. On the other hand, presence of other exogenous variables in the equation tends to vitiate this difficulty somewhat. See Johnston, pp. 309–12, for a discussion of this matter.

TABLE 6—STATIC SIMULATION OF *Full-Effect* VIEW USING EQUATION (20)

70-III to 71-IV	5.352	5.831	−5.353
68-III to 71-IV	3.522	4.243	−3.522

[a,b,c] See Table 2.

full-effect view, although not by a very considerable margin.[18] Notice also that this is the only case where the mean error for the eight quarters, 1968-III to 1970-II, is positive on the full-effect view and negative on the zero-effect view. This means that in general, actual consumption fell between that predicted by the two extremes, rather than outside this interval as had been found earlier.

It thus becomes clear how these three defects of formulation and estimation procedure, when taken all together, would lead one to an erroneous conclusion as to which of the two views of the surcharge was the correct one on the basis of error-term analysis. We may speculate that had Okun used properly specified equations which included a real interest rate variable, had he made the appropriate correction for autocorrelated errors, and had he simulated the two hypotheses with equations estimated using the corresponding definition of income, he could not have escaped the conclusion that the 1968 income tax surcharge did not effectively reduce consumer expenditures.[19]

V. Concluding Comments

Arthur Okun's favorable assessment of the effectiveness of the 1968 temporary income tax surcharge puzzled a number of economists because it seemed to contradict what generally accepted consumer theory would predict for such a measure. His conclusion was doubly perplexing in view of the sharp drop in the savings rate following enactment of the tax, which suggested that most of the adjustment had occurred in financial savings flows. However, a closer and more balanced reading of Okun's findings indicates that his conclusion represents a somewhat overoptimistic interpretation of his own results, and that the actual impact on consumer expenditures was at best about one-fourth of what could be expected from a permanent tax change. And yet, the belief has persisted in many circles that flexible changes in income taxes are a useful and effective instrument of stabilization policy.

---

[18] A truly impartial analysis of the two simulations with equation (20) would actually suggest the hypothesis of 50 percent effectiveness as the most appropriate.

[19] Two further experiments were performed to test the validity of the results reported here. First, the basic equation was estimated using the "correct" procedures over the period 1955-I through 1967-IV, so as to exclude the surcharge period. Dynamic simulations were then run for the full- and zero-effect views over the period following enactment of the surtax. The *RMSE* for the zero-effect view (1.0) continued to be markedly smaller than that for the full-effect view (3.317) over the period 1968-III to 1970-II, and in fact the margin of superiority of the zero-effect view was considerably improved. It might be mentioned that three of Okun's four sets of equations were estimated over observations which included portions of the surcharge period. Secondly, the zero-effect/full-effect hypotheses were tested against the experience of the 1964 tax cut, which *permanently* lowered taxes on business and personal income. Using the basic consumption equation (11) and data on the amount of the tax cut reported in Okun (1968), the full-effect view was found to be superior to the zero-effect view. This result is consistent with what the permanent income theory would predict for a permanent tax change, and it confirms the earlier findings of Ando and Brown, and Okun (1968) that the tax cut was very successful in stimulating consumer spending.

This paper has attempted to lay this myth to rest once and for all by challenging Okun on his own ground of simulating consumption functions over the surcharge period using two extreme definitions of disposable income, one including and one excluding the tax. Equations for consumption and for expenditures on durables—both based on firm theoretical foundations—were estimated and found to have very small coefficients on current income, as well as a low adjustment coefficient on permanent income. This suggested a small short-run impact on consumption of any income tax change—permanent or temporary. Moreover, dynamic error-term analysis demonstrated unequivocally the superiority of the view that the surcharge had no appreciable impact on consumer expenditures. These results were most convincing in the case of consumption, as well as the somewhat more narrow category of consumption of nondurables and services—the very equations which in Okun's analysis had appeared to point most strongly to the superiority of the full-effect view.

Further, the causes of this inconsistency between my findings on the impact of the surcharge on consumption and Okun's were explored. It was found that the combination of failure to adjust for autocorrelated errors, the absence of a real rate of interest variable in the consumption equation, and the erroneous use of an equation estimated with the full-effect definition of income to simulate the zero-effect view would produce the counterintuitive conclusions obtained by Okun. The results described here do not suffer from these deficiencies and are consistent with what theory predicts in the case of a temporary income tax change.

Thus, the evidence of the 1968 surcharge period, far from confirming the general efficacy of temporary changes in income taxes, leads me to be pessimistic regarding the use of flexible tax policy to regulate aggregate demand. It appears that in order to have a significant effect on consumption expenditures, an income tax change must be permanent.

Linear Taxation of Wealth and Wages for Intragenerational Lifetime Justice: Some Steady-State Cases

By J. A. Ordover and E. S. Phelps*

Every paper on the intrageneration redistribution of utilities rightfully makes reference to James Mirrlees. His celebrated paper is the first to study a problem in optimum redistribution without the magic wand of the lump-sum tax. What has proved seminal in that paper is its attractive representation of generational heterogeneity: all worker-consumers can be placed along a one-dimensional continuum with respect to their different efficiencies at producing. Otherwise they are all alike, are equally efficient at consuming, and have the same egoistic utility function that each individual maximizes.

The setting for the analysis is a stark one-period competitive-market economy of bread and leisure. Total output of bread is a constant-marginal-returns function of the aggregate efficiency-weighted man-hours worked—there is no capital. The wage paid to an individual is equal to his product, the efficiency-weighted hours he elects to work. The tax he pays is some function (alike for all individuals) of his wage income. The aggregate tax revenue thus collected is (after subtractions) disbursed to all individuals in the form of a demogrant or lump-sum credit equal for all individuals. Mirrlees's redistributional problem, then, is to find a tax-net-of-demogrant schedule against wage income that maximizes the additive Bentham-Bergson-Fleming social-welfare functional, $\int u(n)^{-\beta} dn$.

It has been the source of some astonishment that no problem in optimum redistribution by non-lump-sum means was even stated, let alone analyzed, until 1971. It is also surprising that the problem that came eventually to be formulated deals with an ornery "detail"—the shape or progressivity of a particular tax schedule. It might have been expected that the economics of redistribution would begin with the analysis of a problem both easier and perhaps more important, to wit: the optimum *mix* of *proportionate* taxes with which to finance redistributive transfers. The marginal utility of departures from linearity in the tax functions could always be left for later attention. Of course, to study such a problem one needs to endow the model economy with more than one factor of production (or more than one consumer good).

Our paper investigates the optimal mix of taxes on two factors of production, capital and (efficiency-weighted) labor. More precisely, we analyze the optimum proportionate taxation of wages and interest, or wages and wealth, with account taken of the public debt. The vehicle for analysis is a blend of Mirrlees's theory of efficiency-weighted labor supply and the life-cycle theory of the supply of wealth found, for example, in the growth model constructed by Peter Diamond.[1]

---

* New York University and Columbia University, respectively. The present paper is an abridged version of a much more extensive working paper cited in the bibliography. Ordover gratefully acknowledges partial support from the National Science Foundation grant to New York University.

The particular optimization problem studied here possesses two special features. The social welfare function we employ expresses the conception of economic justice championed by John Rawls: As a chain is no stronger than its weakest link, social welfare is only as great as the utility of the least well-off, the person or persons having minimum utility. Thus the redistributional optimum is "maximin."

The other feature is a restriction on the dynamics of capital and public debt. The basic notion is also found in a related study of interest taxation by Ordover, in which society is constrained to maintain at some predesignated level the ratio of capital to (geometrically progressing) population. We may not know to what quantity that ratio ought "in justice" to be equal. But whatever that quantity and whenever it is to be attained, society will want then to have that mix of taxes (and resulting demogrant) which is economically just *intragenerationally*, subject to the mandate that fiscal policy preserve this capital-population ratio for the use of future generations. As for the ratio of public debt to population, this too is to be maintained constant from generation to generation, but at a preoptimized rather than arbitrary level.

The present paper is more extensive. We first formulate the "general" (steady-state) problem in which both the public debt and the capital stock per worker are arbitrary constants. We then report our analysis of the optimal tax structure in the aforementioned problem and in the diagonally opposite problem—where the debt per worker is fixed arbitrarily and *capital* per worker is maintained intact at its optimal steady level. Lastly we cite some results obtained for the joint problem of the Golden Rule steady state in which both capital and debt per worker are maintained at their best steady levels.

The paper here also differs with regard to the channels of tax "distortion." As in the original Mirrlees paper, the disincentive effect of taxation falls on the quantity of hours worked (as well as the volume of private saving) rather than the quantity of investment in education, as in the "Polish view" adopted by Ordover and earlier Eytan Sheshinski. As a consequence the supply of efficiency-labor depends not only upon the after-tax wage rate paid to a unit of efficiency-work but also upon the after-tax rate of return to saving—the latter a factor emphasized by several general-equilibrium theorists from Hicks to Lucas.

Our emphasis is on the theory of optimal taxation under market capitalism, with its obvious agenda of questions: Should profits be taxed? Should they be taxed more heavily than wages? Might it be optimal to levy a proportionate wealth tax at a rate exceeding the average rate of profit on capital?[2]

The model has relevance to the theory of market socialism as well as to the welfare economics of capitalist taxation. Karl Marx, Oskar Lange, and some other socialist theorists explained that the returns to capital garnered by the state after payment of wages would be distributed to the people as an equal poll-subsidy/social-divided after subtraction of the state's expenditures on final goods plus any budgetary surplus appropriate to its plans for capital formation. They did not tell us whether a household might be allowed to accumulate wealth claims to future goods; nor did they say what rate of return—positive, zero, or negative—such abstract property, if allowed, ought to be paid for maximum social welfare. The present paper sheds some light on those unanswered questions.

---

[1] Koichi Hamada has studied a different problem in the same setting.

[2] The answers are that "it depends"—depends upon the quantities of capital and public debt per worker and upon the elasticities of factor supplies and demands. The novelty here is that the answers are "technical," being reasoned from an explicit ethical postulate, namely, the maximin criterion. (Use of this analytical approach does not imply indifference or obliviousness to institutions, considered as ends or as means.) In some other approaches, it almost seems as though there is intended to be some kind of justice between people and machines, an animism in which machines usually are held morally inferior to humans.

I. The Model

We first discuss production possibilities, next markets and accounting, then consumer behavior.

A. *Resources and the Production Set*

Each generation lives for two periods. Its members work, if at all, over the first period; they consume, if at all, at the end of each of these two periods. The size of the working age population, N, grows exogenously at the geometric rate $n \geq 0$:

$$(1) \qquad N_{-1} = (1+n)^{-1}N$$

Each per worker variable used below is a certain aggregate divided by current N. We shall be constraining the economy to maintain a steady state in which by definition each such per worker variable is equal from generation to generation.[3]

The per worker quantity of effective labor supplied by the current workforce, denoted by l, is measured in standardized units of "efficiency man-hours." It is an endogenous variable, a function of the after-tax prices and transfers. The efficiency of each person's hours worked is measured by a parameter m that ranges from zero to some $M>0$. The history of any individual of type m is denoted by

$$(2) \qquad x^m = (x_0^m, x_1^m, x_2^m, x_3^m), \qquad m \in [0, M]$$
$$x_0^m + x_3^m = 1, \quad x_j^m \geq 0 \quad \text{all } j$$

where x_0^m is first period leisure, x_i^m is consumption at the end of age i ($i=1, 2$), and x_3^m is "effort" or "worktime" in the first period of life. Worktime is measured in *natural units*, namely as a fraction of the duration of the period.

The basic postulate here is that efficiency differences among individuals are purely labor augmenting; that is, the marginal rate of substitution in production between a man-hour of type m_1 and a man-hour of type m_2 is "constant," given simply by m_1/m_2, independent of the quantities of capital and labor types working alongside. It follows that there exists a labor aggregate which adds up the various man-hours worked when converted to efficiency units. To obtain from the quantity of effort x_3^m, the amount of labor service in efficiency units that it supplies, say l^m, we need only multiply the former by m.[4] Thus we are standardizing on the productivity of the $m=1$ types. Now let the proportion of the population of any and every generation having an efficiency *m or less* be given by a nondecreasing cumulative-distribution function, Φ, with the properties

$$(3) \qquad 0 < \Phi(0) < 1, \ \Phi(M) = 1,$$
$$\Phi(a) \leq \Phi(b) \qquad \text{if } 0 \leq a < b \leq M$$

Then per worker effective labor supplied is[5]

$$(4) \qquad l \equiv \Sigma l^m = \Sigma m x_3^m$$

and the other per worker quantities are

$$(5) \qquad x_i \equiv \Sigma x_i^m, \qquad i = 0, 1, 2, 3$$

We posit a standard one-sector neoclassical net aggregate output function, F. In any steady state with constant k, a certain portion nk of per worker net output,

---

[3] Note that N is the potential number of workers in the market sector, an upper bound on the number who choose to work.

[4] There is no loss of generality in multiplying by m instead of a monotone function of m because the frequency function of m can be adjusted as needed.

[5] For convenience of notation we replace the integral sign by the summation sign.

$F(k, l)$, must be allocated to net investment to keep k constant. Per worker government consumption, $\gamma \geq 0$, is likewise constant. The remaining fraction of net output is available for per worker consumption c.[6] The latter is distributed in a steady state between the per worker consumption of current workers and retired workers thus:[7]

$$c = x_1 + x_2(1+n)^{-1} \tag{6}$$

Hence steady-state growth with constant k entails the *capital constraint*

$$F(k, l) - x_1 - x_2(1+n)^{-1} = \gamma + nk \equiv \text{constant} \geq 0 \tag{7}$$

B. *Market Organization, Prices, and Social Accounting*

We turn now to the demand side of the model and to the market aspects.[8] There are three goods and we may think of two perfect markets: a labor market where labor (homogeneous after conversion to efficiency units) is exchanged for present consumables, and a capital market where savings (unexercised claims to present goods) are traded for claims to future goods.

So far as proportionate taxation of households' market demands and supplies are concerned, there is no loss of generality in our assuming that expenditures on the commodities (x_1 and x_2) are untaxed. Hence let us consider a proportionate tax rate on wage income, denoted τ_w, and a proportionate tax rate on profits (or interest) from saving, τ_r. (We can also entertain the possibility of a proportionate tax on private wealth.) In the "natural" interpretation, then, our two markets *and* taxation determine *four* relative prices of the two factors: The before-tax real wage rate w, the after-tax real wage rate ω, the rate of return before tax on real private savings r, and the after-tax rate of return ρ. The term "real" denotes deflation by the "money" price of presently consumable commodities, and the term "wage rate" refers to the rate for a standard individual, the real wage per efficiency unit of labor.

We postulate the universal lifetime income guarantee, or demogrant, which comes in two installments, β_1 and β_2. For the moment we think of β_1 and β_2 as each nonnegative. Accordingly there is an obvious lifetime budget constraint for households of *any* type m which, when aggregated, yields the relation

$$(1+\rho)^{-1}(x_2 - \beta_2) = \omega l - (x_1 - \beta_1) \tag{8}$$

Note that the right-hand side of (8) equals the per worker purchases of wealth by the present working-age generation. But aggregate wealth in a steady state must grow geometrically at rate n. Therefore, if d denotes the per worker stock of public debt existing at the beginning of the period, and so $k+d$ is the per worker quantity of wealth, then the workers must purchase $(1+n)(k+d)$ of wealth in order that per worker wealth be unchanged next period. Hence the *private wealth constraint:*

$$(1+\rho)^{-1}(x_2 - \beta_2) = (1+n)(k+d) = \text{constant} > 0 \tag{9}$$

Equations (8) and (9) imply the *social budget constraint:*

$$x_1 + \frac{x_2}{1+n} = \beta_1 + \frac{\beta_2}{1+n} + \omega l + \rho(k+d) - n(k+d) \tag{10}$$

---

[6] Obviously the requirements of growth and public expenditure may be too great to admit a solution with nonnegative consumption and efficiency-weighted leisure.

[7] In a state of steady growth at rate n, the (future) second-period consumption x_2 of the present generation of first-period people is $(1+n)$ times the second-period consumption of people now in their second period.

[8] For an extensive discussion of these matters, the interested reader may consult the authors' working paper.

This states that, with regard to aggregates, consumption equals disposable income *less* private saving. Let us also observe that, expenditure taxes nil, national output equals national income:

$$(11) \qquad rk + wl = F(k, l)$$

Hence, from (7)

$$(12) \quad x_1 + \frac{x_2}{1+n} = rk + wl - \gamma - nk$$

Subtracting (10) from (12) we obtain the government's income statement

$$(13) \quad (r-\rho)k + (w-\omega)l - \rho d = \beta_1 + \frac{\beta_2}{1+n} + \gamma - nd$$

The left-hand side is net tax revenue—net, that is, of after-tax interest on the public debt; this must cover public benefits and expenditures *less* the budgetary deficit. In (13), the deficit is constrained to maintain the given debt-worker ratio d_0, however determined—whether predetermined by actual history or hypothetically optimized. Hence (13) expresses a *public debt constraint* that, using (11), we may state more explicitly and analogously to (7) in the form

$$(14) \quad F(k,l) - \rho(k+d) - \omega l - \beta_1 - \frac{\beta_2}{1+n} = \gamma - nd_0 = \text{constant}$$

The capital constraint in (7) prescribes a certain amount of national saving while the debt constraint prescribes how much of this shall be public saving, $-nd_0$, in lieu of private saving.[9]

C. *Consumer Behavior*

Regarding consumers, we suppose that households of any type m choose $x^m = (x_1^m, x_2^m, x_3^m)$ to maximize utility $u(x^m)$, which is independent of m, subject to their budget constraint—like (8), expressed here in terms of present value or discounted prices, $q^m = (q_1, q_2, q_3^m)$. The latter are defined thus:

$$q_1 \equiv 1, \quad q_2 \equiv (1+\rho)^{-1}, \quad q_3^m \equiv m\omega, \quad q_3 \equiv$$

In these terms the maximization problem is

$$(15) \quad V^m(q^m; \beta_1, \beta_2) = \max_{\{x^m\}} \left\{ u(x^m) - \alpha^m \left[\sum_1^2 q_i^m (x_i^m - \beta_i) - q_3^m x_3^m \right] \right\}$$

V^m is the indirect utility function, homogeneous of degree zero in the prices, with derivatives

$$(16) \qquad \begin{aligned} \partial V^m / \partial q_3^m &= \alpha^m x_3^m \\ \partial V^m / \partial q_2^m &= -\alpha^m x_2^m \\ \partial V^m / \partial \beta_i &= \alpha^m q_i \qquad i = 1, 2 \end{aligned}$$

where the Lagrange multiplier $\alpha^m > 0$ is the marginal utility of (present) money.

From the households' utility maximizations we can obtain the individual demand functions for x_1^m, x_2^m, and the individual supply functions for saving $\sigma^m \equiv q_2(x_2^m - \beta_2)$ and effective labor l^m. Aggregating these demands and "factor" supplies, we obtain the per worker market demands for x_1 and x_2, and the market supplies of labor l and wealth $\sigma \equiv q_2(x_2 - \beta_2)$. These market demands and supplies are each a function, given β_2, of the triplet $(1, q_2, q_3, \beta_1)$. These market functions must obey the lifetime budget constraint in (8), which we write here

$$(8') \quad q_2(x_2 - \beta_2) = q_3 l - x_1 + \beta_1 \equiv \sigma$$

Let σ_i denote $\partial\sigma/\partial q_i$, and similarly for l_i, x_{1i}, and x_{2i}. Then differentiation of this budget equation yields

---

[9] The constraint on public saving in (14) could be replaced by the constraint on *current* private *all-generation* saving in (10) or, as well, by the constraint on after-interest private wealth in (9). But the overlife constraint on the present generation only is no substitute for these social constraints.

$$
\begin{aligned}
(17)\quad x_2 - \beta_2 + q_2 x_{22} &= 0 + q_3 l_2 - x_{12} \equiv \sigma_2 \\
q_2 x_{23} &= l + q_3 l_3 - x_{13} \equiv \sigma_3 \\
q_2 x_{2\beta} &= 1 + q_3 l_\beta - x_{1\beta} \equiv \sigma_\beta
\end{aligned}
$$

To narrow the analysis that follows, we wish to place some natural restrictions on the functions x_1, x_2, l, and σ. Thus, we shall suppose that all goods are strictly noninferior, subject to some inessential qualifications at boundaries, so that

$$
\begin{aligned}
(18)\quad & x_{i\beta}>0,\ 0<q_i x_{i\beta}<1, \quad i=0, 1, 2;\ x_{3\beta}<0 \\
& l_\beta<0,\ \sigma_\beta>0 \qquad (\text{for } q_2<\infty,\ q_3>0)
\end{aligned}
$$

Concerning the wealth supply function we shall assume, *first*, that $\sigma(1, \infty, q_3, \beta_1)=0$: that is, no one will save at the confiscatory $\rho=-1$. (Since there may be public saving, the latter does not guarantee that $\rho=-1$ is inoptimal.) *Second*, a rise of the wage rate increases saving everywhere. Then, for all $q_2<\infty$ and $q_3>0$,[10]

$$
(19)\qquad \sigma_3(1, q_2, q_3, \beta_1) = q_2 x_{23} > 0
$$

Third, because the "marginal propensities" $q_i x^m_{i\beta}$ are between zero and one, by noninferiority, we can also argue that

$$
(20)\quad \sigma_2(1, q_2, q_3, \beta_1) = \begin{cases} <0 & \text{at } q_2 = \infty \\ >0 & \text{at } q_2 = 0 \end{cases}
$$

The argument is that σ increases with ρ in the neighborhood of $\rho=-1$, because there is no income effect to counter the positive substitution effect of larger ρ. Hence, σ "bends backward" at sufficiently large ρ (small q_2) in the (σ, ρ) plane and likewise in the (σ, q_2) plane.

Concerning the labor supply function we shall assume, *first*, that $l(1, q_2, 0, \beta_1)=0$: no one will work at $\omega=0$. *Second*, we specify that

$$
(21)\quad l_2(1, q_2, q_3, \beta_1) = \begin{cases} \lesseqgtr 0 & \text{at } q_2 = \infty \\ >0 & \text{at } q_2 = 0 \end{cases}
$$

As $q_2\to\infty$ the income effect of higher q_2 becomes negligible, so l_2 has the sign of the cross-substitution effect, positive or negative. If negative then there must hold a *Hicks-Lucas* effect $l_2<0$ at sufficiently large q_2—that is, labor supply must be increasing in ρ around $\rho=-1$. As $q_2\to 0$, $x_2\to\infty$, so the income effect of a rise in q_2 is presumed to be decisive, decreasing leisure and increasing labor supply, whatever the sign of the cross-substitution effect. We shall refer to $l_2>0$ as the *anti-Hicks-Lucas effect.*

Finally, we have

$$
(22)\quad l_3(1, q_2, q_3, \beta_1) = \begin{cases} >0 & \text{at } q_3 = 0 \\ =0 & \text{at } q_3 = \infty \end{cases}
$$

The labor supply function is increasing at $q_3=0$, where $l(\cdot)=0$, and it may bend backward at sufficiently large q_3.

II. The Analysis

Our problem is the selection of tax rates on wages and interest (or wealth) so as to maximize over feasible steady states the minimum level of utility, $\min_m V^m(\cdot)$. This bottom utility must equal $V^0(\cdot)$, for no one of any type m could do worse than the $m=0$ types. As is widely done in the optimal taxation literature, we actually maximize $V^0(\cdot)$ with respect to the after-tax factor rewards (ρ, ω) or equivalently (q_2, q_3), as if the optimization were for a socialist state. This is merely a calculating device. To each pair (ρ, ω) there corresponds a unique tax-rate pair (τ_r, τ_w) and the latter is often readily solved for.

This maximization is subject in the "general" case to any *two* of the three constraints—(7) on capital, (10) on private wealth supply, (14) on public debt. In terms of the first two of these constraints, the general problem can be expressed for any given β_2 as

$$
(23)\qquad \underset{\{q_2, q_3, \beta_1\}}{\text{maximize}}\ V^0(q_2, q_3, \beta_1; \beta_2)
$$

---

[10] An interpretation of this inequality, though not a necessary implication, is that leisure and second-period consumption are everywhere net substitutes.

subject to

$$(23') \quad nk = F(k, l) - (q_3 l + \beta_1 - \sigma) - (q_2^{-1}\sigma + \beta_2)(1 + n)^{-1} - \gamma \equiv J(q_2, q_3, \beta_1; k, \beta_2)$$

$$(23'') \quad (1 + n)(k + d) = q_2(x_2 - \beta_2) \equiv \sigma(q_2, q_3, \beta_1; \beta_2)$$

In (23′) we have obviously substituted for x_1 from the lifetime budget constraint (8′) in terms of l and σ. Similarly, we represent x_2 by the same function of $(q_2, q_3, \beta_1, \beta_2)$, namely $q_2^{-1}\sigma + \beta_2$, as gives the *ex ante* x_2 of the current workers on the ground that the prices established must be the same over generations in any steady state.

The first-order conditions for a maximum in (23) involve the first derivatives V_2^0, V_3^0, and V_β^0 of the indirect utility function V^0. We have

$$(24) \quad \overset{0}{V}_2 = -(\overset{0}{x}_2 - \beta_2)\overset{0}{V}_\beta, \quad \overset{0}{V}_3 = \overset{0}{l}\overset{0}{V}_\beta = 0, \quad \overset{0}{V}_\beta > 0$$

Here, V_β^0 is the marginal utility of β_1 to the poor; V_3^0 is zero because the $m=0$ type cannot earn wages.

The sign of V_2^0 is indeterminate until β_2 is specified. We shall confine the analysis reported here to the following special case: The parameter β_2 has been fixed such that, *at the maximum in* (23),

$$(25) \quad \beta_2 = \overset{0}{x}_2 \geq 0$$

To motivate (25) it might be argued that the government would want β_2 large enough to lift from the poor the burden of providing for their old age out of their β_1 yet not so large that the poor are induced to borrow against future β_2 for additional first-period consumption.

Consequently $V_2^0 = V_3^0 = 0$ in the neighborhood of the maximum. A change of q_2 or q_3 in this neighborhood will therefore increase $V(\cdot)$ only by increasing β_1 via one of the constraints. Hence the pair (q_2, q_3) which maximizes $V(\cdot)$ in (23) must be simultaneously maximizing β_1.

The maximization of β_1 may be formulated as a problem in what might be termed "stationary programming." Noting that $J_\beta < 0$, let us assign β_1 to meet the capital constraint in (23′). Then choose (q_2, q_3) to maximize β_1 so determined, subject to the wealth constraint in (23″). (Because $\sigma_3 > 0$ it is also natural to think of q_3 as tied to the wealth constraint, thus making q_2 the variable free for decision.) The *maximum* value of β_1 depends only on the exogenous k and d (given β_2 and the other parameters) and is denoted $b(k, d)$:

$$(26) \quad b(k, d) = \max_{\{q_2, q_3\}} \beta_1$$

subject to (23′) and (23″).

From (26), (23′), and (23″) we then obtain the functional equation

$$(27) \quad 0 = \max_{\{q_2, q_3\}} \{J(q_2, q_3, b(k, d); k) - nk - \lambda[\sigma(q_2, q_3, b(k, d)) - (1+n)(k+d)]\}$$

In this maximization, $b(k, d)$ and the Lagrange multiplier $\lambda(k, d)$ are "constants," independent of (q_2, q_3), being functions only of the predetermined state variables (k, d) and the other parameters.

The interpretation of (27) is clear. To maximize β_1, (q_2, q_3) are chosen, subject to $\sigma = (1+n)(k+d)$, to make $J(\cdot)$ as large as possible. For since $J_\beta < 0$, the larger is $J(\cdot)$ at any β_1, the higher is the β_1 that keeps $J(\cdot) = nk$.

At the maximum β_1 the following first-order conditions hold:

$$(28a) \quad J_2 - \lambda\sigma_2 = 0, \qquad J_3 - \lambda\sigma_3 = 0$$

$$(28b) \quad J_\beta - \lambda\sigma_\beta \leq 0$$

The argument for (28b) is that if it did not hold there would be room for some free self-sustaining rise of β_1 which would increase $\lambda\sigma(\cdot)$ by so much as to permit (via q_2 and q_3) a net increase of $J(\cdot)$, hence still larger β_1; but such is impossible at the maximum β_1.

By equating to zero the total derivative with respect to d of the right-hand side of (27) we also obtain the "marginal worth" of an increase in the debt per worker:

$$b_d(k, d) = \frac{\lambda(1+n)}{-J_\beta + \lambda\sigma_\beta} \tag{29}$$

It follows from (28b) that λ and $b_d(k, d)$ are like-signed—positive, negative, or zero as the debt is too small, too large, or just right. It may be noted that λ and hence $b_d(k, d)$ have the sign of J_3 by virtue of (28a) and the specification that $\sigma_3 > 0$. If optimal $J_3 < 0$, for example, a larger debt, by entailing larger $\sigma(\cdot)$ and therefore larger q_3 at each q_2, would result in smaller $J(\cdot)$ at any given β_1 and thus imply a reduction of maximum β_1, that is, $b_d(k, d) < 0$.

A. *Optimal Taxes with Arbitrary Debt and Capital*

Space permits only fleeting attention here to the tax implications of the general problem as studied in our working paper. The succeeding sections on the more restrictive problems will serve to indicate the kinds of propositions developed and to convey the analytics employed.

For use in Sections IIA, B, and C, respectively, we define these *specific* (as distinct from *ad valorem*) tax rates:

$$\begin{aligned} \text{(30a)} \quad t_\lambda &= (1-\lambda)(1+\rho)^{-1} - (1+n)^{-1} \\ &= [n - \lambda(1+n) - \rho]q_2(1+n)^{-1} \\ \text{(30b)} \quad t_n &= (1+\rho)^{-1} - (1+n)^{-1} \\ &= (n-\rho)q_2(1+n)^{-1} \\ \text{(30c)} \quad t_r &= (1+\rho)^{-1} - (1+r)^{-1} \\ &= (r-\rho)q_2(1+r)^{-1}, \qquad r \equiv F_k \\ \text{(30d)} \quad t_w &= w - \omega, \quad \tau_w = t_w\omega^{-1} \quad w \equiv F_l \end{aligned}$$

Evidently t_n is a kind of "shadow" tax rate. It measures the wedge between ρ, the after-tax rate of return to saving, and n, the "natural" rate of interest—essentially, the marginal rate of transformation between x_1 and x_2 in the equation $J - nk = 0$. For $\lambda \neq 0$, however, t_λ is the analogous shadow tax rate. It appears if we write our maximand in (27) as

$$\text{(27}') \quad \underset{\{q_2, q_3\}}{\text{maximize}}\; F(k, l) - q_3 l + t_\lambda x_2 + \text{constant}$$

where again the functions $l(q_2, q_3, \beta_1)$ and $x_2(q_2, q_3, \beta_1)$ are to be evaluated at $\beta_1 = b(k, d)$. The derivative of the maximand with respect to efficiency-labor is $t_w = F_l - q_3$ and the derivative with respect to x_2 is t_λ.

The first-order conditions for a maximum in (28) can thus be expressed as:

$$\begin{aligned} \text{(31)} \quad l_2 t_w + x_{22} t_\lambda &= -(1-\lambda)(x_2 - \beta_2) \\ l_3 t_w + x_{23} t_\lambda &= l \\ l_\beta t_w + x_{2\beta} t_\lambda &\leq 1 \end{aligned}$$

While a few results, largely in the nature of logical possibilities, are derivable from (31), we proceed now to the more restrictive problem with preoptimized debt in Section B and with preoptimized capital in Section C.[11]

B. *Optimal Taxes with Optimized Debt*

In the problem here, public debt per worker is a free variable. The portion of investment comprised of *private* saving is unconstrained, subject only to *nonnegativity* of private wealth supply. In the special case defined in (25) therefore, where $V_2^0 = 0$, the optimal tax problem may be expressed as

---

[11] An amusing footnote to the general problem of exogenous k and d is its Cantabridgian theory of the functional distribution of *disposable* national income between interest, $\rho(k+d)$, and wages, ωl:

> *Cambridge Lemma*: Because all interest (after tax) is consumed while some wages (after tax) are saved, the functional distribution of income (after tax), $\{\rho(k+d), \omega l\}$ must favor wages just enough to insure that private saving equal $n(k+d)$.

Of course, it is the factor unit rewards, ω and ρ, which are of policy significance.

$$nk = \max_{\{q_2, q_3\}} J(q_2, q_3, b(k); k) \tag{32}$$

subject only to

$$0 \leq q_2(x_2 - \beta_2) \equiv \sigma(q_2, q_3, b(k)) \tag{32'}$$

where $b(k)$ is the maximized β_1.

At an interior solution, where the nonnegativity constraint is not binding, the first-order conditions are

$$J_2 = 0, \quad J_3 = 0; \quad J_\beta < 0 \tag{33}$$

A subsequent proposition will address the possibility of a corner solution at $\sigma(\cdot) = 0$.

The following properties of the solution can now be shown.

PROPOSITION B1: *Optimal* $\omega > 0$ *whether or not optimal* $\sigma(\cdot) > 0$.

If $\omega = 0$, $l = 0$ whence $J(\ ) < 0 < nk$ which is inadmissible.

PROPOSITION B2: *The corner solution at* $\sigma(\cdot) = 0$ *occurs if and only if optimal* $\rho = -1$.

First note that $\sigma(\rho, \omega, \beta) = 0$ for all ω and β if $\rho = -1$, that is, $q_2 = \infty$. Conversely, the existence of a solution at $\sigma(\cdot) = 0$ implies $\rho = -1$. For $\omega > 0$ by Proposition B1, $\beta_1 > 0$ for the solution to permit $0 < x_1^0 (= \beta_1)$, while $\sigma(\rho, \ \omega > 0, \ \beta_1 > 0) > 0$ for all $\rho > -1 (q_2 < \infty)$. So the optimal allocation will display property owning if optimal $\rho > -1$.

PROPOSITION B3: *Optimal* $l_3 > 0$ *whether the solution is at the corner or is interior.*

At an interior optimum, $J_3 = 0$. At the corner solution where $\sigma(\cdot) = 0$, $\rho = -1$ so that $\sigma_3 = 0$ for all ω. Hence $J_3 = 0$ at a corner solution as well. Recall now that

$$J(\cdot) = F(k, l) - x_1 - x_2(1 + n)^{-1} - \gamma$$

Since $F_l > 0$, $x_{13} > 0$, and $x_{23} \geq 0$, $l_3 \leq 0$ would imply $J_3 < 0$, a contradiction. The economics here is that at an allocation on some backward-bending segment of the labor-supply curve, where $l_3 < 0$, it would be possible to drop ω to a rising segment for a gain in $J(\cdot)$ at the initial β_1 and thus obtain some increase in β_1 without violating $J(\cdot) = nk$.

PROPOSITION B4: *Optimal* $\rho = -1$ *implies* $l_2 \geq 0$ *(no Hicks-Lucas effect) in that neighborhood. Hence the presence of a Hicks-Lucas effect of larger* ρ, *at least around* $\rho = -1$, *is sufficient to rule out a corner solution.*

Using the budget relation $x_1 = \omega l + \beta_1 - (1+\rho)^{-1}(x_2 - \beta_2)$ we write

$$\begin{aligned} J(\cdot) = {} & F(k, l) - \omega l - \beta_1 \\ & + (x_2 - \beta_2)(1 + \rho)^{-1} \\ & - x_2(1 + n)^{-1} - \gamma \end{aligned} \tag{34}$$

At the corner where $\rho = -1$ and thus $x_2 = \beta_2$ the first-order conditions for a constrained maximum are

$$\left.\frac{\partial J}{\partial \rho}\right|_{\rho=-1} = (F_l - \omega)\frac{\partial l}{\partial \rho} + t_n \frac{\partial x_2}{\partial \rho} \leq 0 \tag{35a}$$

$$\left.\frac{\partial J}{\partial \omega}\right|_{\rho=-1} = (F_l - \omega)\frac{\partial l}{\partial \omega} - l = 0 \tag{35b}$$

recalling that $x_{23} = 0$ at $\rho = -1$. Now $t_n \equiv (1+\rho)^{-1} - (1+n)^{-1} > 0$ at $\rho = -1$. And $t_w = F_l - \omega > 0$ since $l > 0$ for a solution and $l_3 > 0$ by Proposition B3. Also $\partial x_2/\partial \rho \geq 0 (x_{22} \leq 0)$ around $\rho = -1$. Hence (35a) implies $\partial l/\partial \rho \leq 0$ which is non-Hicks-Lucas. Actually, if $\partial x_2/\partial \rho > 0$, $\partial l/\partial \rho < 0$.

In the remainder of this section we shall be assuming that the solution is interior at some $\sigma(\cdot) > 0$. This means that the labor-supply function is Hicks-Lucas at least around $\rho = -1$. Then $\rho > -1$ and the first-order conditions in (33), expressed in terms of (q_2, q_3, β_1) and the tax rates (t_w, t_n), are

$$l_2 t_w + x_{22} t_n = -(x_2 - \beta_2) < 0 \tag{36a}$$

$$l_3 t_w + x_{23} t_n = l > 0 \tag{36b}$$

$$l_\beta t_w + x_{2\beta} t_n < 1 \tag{36c}$$

PROPOSITION B5: *Either t_w or t_n or both are positive.*

Since $l_3>0$ and $x_{23}>0$, $t_n\leq 0$ implies $t_w>0$ from (36b).

PROPOSITION B6: *If $l_2\geq 0$ at the optimum, then $t_n>0 (\rho<n)$.*

Assume the contrary, that $t_n\leq 0$. Then $t_w<0$ when $l_2\geq 0$ by (36a). But $t_w>0$ if $t_n<0$ by (36b)—Proposition B5. Hence $t_n>0$ if $l_2\geq 0$.

To the same end, we may solve (36a) and (36b) for t_n and t_w:

$$(37)\qquad t_n=\frac{ll_2+(x_2-\beta_2)l_3}{l_2x_{23}-l_3x_{22}}$$

$$t_w=\frac{-(x_2-\beta_2)x_{23}-lx_{22}}{l_2x_{23}-l_3x_{22}}$$

If $l_2\geq 0$, then the common denominator is positive and so is t_n. But t_w may apparently be of either sign.

The presence of anti-Hicks-Lucas effect $l_2\geq 0$ at the optimum rules out $\rho>n$ as we have just seen. One might expect also that it precludes a solution where σ is backward-bending: that is, $\partial\sigma/\partial\rho<0$ or $\sigma_2>0$. But we can prove only the conditional statement:

PROPOSITION B7: *Should the optimum be anti-Hicks-Lucas ($l_2\geq 0$), then $\sigma_2<0$ if optimal $t_w\geq 0$.* COROLLARY: *If $\sigma_2\geq 0$ at such optimum, then $t_w<0$.*

To prove, we note that

$$(38)\quad J_2=t_wl_2+\sigma_2-(1+n)^{-1}x_{22}=0$$

Then $t_w\geq 0$ and $x_{22}<0$ imply $\sigma_2<0$. The corollary is immediate and may be interpreted as follows: An increase of ρ within any backward-bending stretch of σ must, apart from its effect on labor supply, reduce $J(\cdot)$ because it must reduce $t_n(x_2-\beta_2)$—certainly as long as $t_n>0$, as it must be when $l_2\geq 0$. If this increase is optimal to make when it would reduce labor supply ($\partial l/\partial\rho<0$), it must be that t_w is negative.

By the same reasoning, if $\partial l/\partial\rho>0$, pushing ρ into a backward-bending stretch of σ would seem to be plausible only if $t_w>0$, so that q_3l rises by less than $F(\cdot)$; but here we have to watch for the possibility that $t_n<0$ so that x_{22} is another "plus" in the case for high ρ. However, we can prove

PROPOSITION B8: *If $\sigma_2\geq 0$ at the optimum, then $l_2t_w<0$ so that t_w and $\partial l/\partial\rho$ are like-signed.*

From (38) it follows that $t_wl_2=-\sigma_2+(1+n)^{-1}x_{22}<0$.

The foregoing analysis may have left the false impression that l_2 can be of any sign *independently* of ρ and ω. In our model, the Hicks-Lucas effect $l_2<0$ requires that first-period leisure and second-period consumption are net substitutes, in the aggregate at any rate, and this substitution effect of a rise of ρ, which encourages less leisure, overcomes the income effect, which encourages more leisure. Our assumptions so far pose no bar to considering the possibility that at least for all $\rho<n$ the income effect is swamped by the substitution effect so that in that region $l_2<0$ (Hicks-Lucas). This leads to the result:

PROPOSITION B9: *If $l_2<0$ for all $\rho<n$, then optimal $l_2<0$. It is then possible that optimal $\rho>n$ and $t_w>0$.*

The proof is by contradiction. If optimal $l_2\geq 0$, optimal $\rho<n$ (Proposition B6). But, by supposition, $l_2<0$ at every $\rho<n$. Hence optimal $l_2\geq 0$ is impossible. As before, optimal $l_2<0$ leaves the signs of t_n and t_w indeterminable from (36a)–(36c). However, it is clear from (37) that $t_n>0$ for some $l_2<0$.

Suppose the optimum is indeed such that $t_n<0$ ("machines are subsidized") and $t_w>0$ ("toil is taxed"). Where is the justice in that? The only possible justification for raising ρ beyond the biologic rate n is its Hicks-Lucas stimulus to the supply of output, $F(k, l)$. Undoubtedly many critics of the "socialist" goal of propertylessness, and of the "humanist" opposition to interest income, have had this "model" implicitly in mind: Prohibitions against property holding and heavy taxation of interest *may* so dampen income-earning incentives as to be inefficient in the maximization of any Bergson-type social welfare function.

Finally, we state the following results although the proof will have to be omitted here:

PROPOSITION B10: *If first-period leisure and second-period consumption are "independent" goods or else net complements for all households at the optimum, then* $t_n > 0$ *and* $t_w > 0$.

C. *Optimal Taxes with Optimized Capital*

In the previous section, capital was fixed and the per capita debt is free to be set at its optimal stationary level. The latter is calculable by regarding d as endogenously determined by $(1+n)^{-1}\sigma(\cdot)-k$. In Act 2, as it were, the shoe is on the other foot. The debt per worker is fixed and capital per worker is allowed to realize its optimal level, determined by

$$(39) \quad k = (1+n)^{-1}\sigma(\cdot) - d \equiv \sigma^*(\cdot) - d$$

when evaluated at optimal q_2, q_3, β_1. It may be noticed that the notion of a welfare-maximizing steady-state k is just the Golden Rule exercise with the new wrinkle of a government deficit constraint. But it is with the optimal taxes in this steady state that we are concerned.

In the special case where $V_2^0 = \beta_2 - x_2^0 = 0$, our new problem may be formulated analogously to (32):

$$(40) \quad -nd = \max_{\{q_2, q_3\}} P(q_2, q_3, b(d); d)$$

in which $P(\cdot)$ is defined as the government's algebraic budgetary surplus per worker:

$$(41) \quad P(\cdot) \equiv F[(\sigma^* - d), l] - q_2^{-1}(1-q_2)\sigma^* - q_3 l - \beta_2(1+n)^{-1} - \gamma - \beta_1$$

$P(\cdot)$ is to be evaluated at the maximum $\beta_1 = b(d)$. The maximization in (40) is constrained by $\sigma^* - d = k \geq 0$ and $\sigma^* \geq 0$. In the following analysis it is assumed that an interior solution exists that makes both k and σ^* positive.

The first-order conditions for an interior maximum are

$$(42) \quad P_2 = 0, \qquad P_3 = 0, \qquad P_\beta \leq 0$$

Equations (41) and (42) yield

$$(43a) \quad l_2 t_w + x_{22}(1+r)(1+n)^{-1}t_r = -(1+r)(1+n)^{-1}(x_2 - \beta_2) < 0$$

$$(43b) \quad l_3 t_w + x_{23}(1+r)(1+n)^{-1}t_r = l > 0$$

$$(43c) \quad l_\beta t_w + x_{2\beta}(1+r)(1+n)^{-1}t_r \leq 1$$

where, recalling (30c), $t_r \equiv (r-\rho)(1+\rho)^{-1} \cdot (1+r)^{-1}$ and $r = F_k$.

A less cumbersome way to write (43) uses $\rho = q_2^{-1}(1-q_2)$ and $\omega = q_3$:

$$(44a) \quad \frac{\partial l}{\partial \rho} \cdot (F_l - \omega) + \frac{\partial \sigma^*}{\partial \rho}(F_k - \rho) = \sigma^*$$

$$(44b) \quad \frac{\partial l}{\partial \omega} \cdot (F_l - \omega) + \frac{\partial \sigma^*}{\partial \omega}(F_k - \rho) = l$$

$$(44c) \quad l_\beta \cdot (F_l - \omega) + \sigma^*_\beta (F_k - \rho) \leq 1$$

We state the following results with remarks on the proofs.

PROPOSITION C1: *Neither* $\rho = -1$ *nor* $\omega = 0$ *is optimal.*

This follows from our assumptions that $\sigma^* > 0$ and $\sigma^* - d > 0$.

PROPOSITION C2: *If optimal* $l_3 < 0$, *then* $t_r > 0$.

In (43b), $t_w l_3 - l < 0$ if $l_3 < 0$ because $l + l_3 q_3 > 0$.

PROPOSITION C3: *Either* $t_r > 0$ *or* $t_w > 0$ *or both.*

If $l_3<0$, $t_r>0$. If $l_3\geq 0$, $t_w>0$ or $t_r<0$ by (43b). If $l_3<0$, nothing new follows if also $l_2\geq 0$. But

PROPOSITION C4: *If optimal* $l_2>0$, *then* $t_r>0$.

If $t_w\leq 0$, $t_r>0$ by C3. If $t_w>0$, and $l_2>0$, then $t_r>0$ by (43a).

Section B was greatly simplified by the result that $l_3>0$. It hinged on the result that $\partial[F(k,\ l)-\omega l]/\partial q_3$ is positive. In a symmetrical world, it would be true here that $\sigma_2<0$, that is, $\partial\sigma/\partial\rho>0$. The hitch is apparently that we do not *generally* have $\partial[F(k,\ l)-\omega l]/\partial q_2$ positive. Hence very low q_2 might be repaid from the labor end. Nevertheless, suppose optimal $t_w l_2\geq 0$. Then (43a) yields

$$(45)\quad [q_2-(1+r)^{-1}]x_{22}+x_2-\beta_2 = -\,l_2t_w(1+r)^{-1}(1+n)<0$$

Hence, from (17),

$$(46)\quad \sigma_2=-\,l_2t_w(1+r)^{-1}(1+n) + (1+r)^{-1}x_{22}<0$$

This leads to the result:

PROPOSITION C5: *If optimal* $l_2t_w\geq 0$, $\sigma_2<0$ (*non-backward-bending solution*). *If* $\sigma_2\geq 0$, *then* t_w *and* $\partial l/\partial\rho(\neq 0)$ *are like-signed.*

For completeness, we solve for $r-\rho$ and t_w from (44a) and (44b):

$$(47)\quad r-\rho=\frac{l\dfrac{\partial l}{\partial\rho}-\sigma^*\dfrac{\partial l}{\partial\omega}}{\dfrac{\partial l}{\partial\rho}\dfrac{\partial\sigma^*}{\partial\omega}-\dfrac{\partial l}{\partial\omega}\dfrac{\partial\sigma^*}{\partial\rho}}$$

$$t_w=\frac{\sigma^*\dfrac{\sigma\sigma^*}{\partial\omega}-l\dfrac{\partial\sigma^*}{\partial\rho}}{\dfrac{\partial l}{\partial\rho}\dfrac{\partial\sigma^*}{\partial\omega}-\dfrac{\partial l}{\partial\omega}\dfrac{\partial\sigma^*}{\partial\rho}}$$

A nominally identical "formula" for t_w can be obtained for the problems posed in Section A and Section B. Analysis of (47) adds nothing to what has preceded.

D. *Optimal Taxes with Optimized Capital and Debt*

When the debt is free, the problem of optimal taxation is to maximize V^0 subject to $J(\cdot)=nk$. Because $V^0(q_2,\ q_3,\ \beta_1,\ \beta_2)$ is not a function (directly) of k, the latter influences maximum $V^0(\cdot)$ only through its impact on the investment constraint. If $F_k-n>0$, an increase of k increases maximum feasible β_1 for any q_2, q_3, β_2. Hence at optimal k, $F_k=n$. If $F_k\neq n$, some change of k could permit higher β_1, hence greater $V^0(\cdot)$ for fixed q_2, q_3, and β_2, so that k could not be the best sustainable, steady k.

The argument is easily formalized for the special case using (27) of Section A. Optimized debt implies

$$(48)\qquad 0=b_d(k,\ d)=\frac{\lambda(1+n)}{-J_\beta+\lambda\sigma_\beta}$$

Hence $\lambda=0$. Also optimal k implies

$$(49)\quad 0=b_k(k,\ d)=\frac{F_k-n+\lambda(1+n)}{-J_\beta+\lambda\sigma_\beta}$$

Therefore when both k and d are optimized

$$(50)\qquad F_k(k,\ l)=n$$

The Golden Rule path, unconstrained by a nonoptimal debt requirement, has a technological characterization in terms of the *capital-labor ratio* k/l, similar to the Golden Rule path's characterization in *technocratic* models where no attention is paid to the institutions, fiscal or otherwise, needed to sustain that path and other parallel, steady-state paths.

Is this result surprising? In one respect, no. To maximize V^0 and β_1, we desire efficiency in production; the Golden Rule path is, in a sense, the *most* "efficient" of all sustainable paths. It leaves the largest slack for consumption per head, and thus for β_1 which "absorbs" this slack.

But in another respect it is surprising and a little misleading. One might have thought that a larger capital stock would impose larger "deadweight" frictional costs beyond the increase in steady-state investment nk; perhaps higher tax *rates* t_w and t_n eventually might be needed to ensure the increase in nk as k approached its technocratic level because effective labor per head l is smaller than what one supposes it would be if taxation were (optimally) lump sum. Actually, institutions do indeed affect the magnitudes of k and l on the Golden Rule path. But they do so equiproportionately. Thus they leave $F_k=n$ and $F_l=\Psi(F_k)=\Psi(n)$, the function Ψ describing the factor price frontier.

With regard to the Golden Rule debt level, if optimal σ^* is less than (greater than) Golden Rule k, then optimal d is negative (positive). To analyze the optimal tax mix, we use $n=r$ and (36a)−(36c) to obtain

$$l_2 t_w + x_{22} t_r = -(x_2 - \beta_2) < 0 \tag{51a}$$

$$l_3 t_w + x_{23} t_r = l > 0 \tag{51b}$$

$$l_\beta t_w + x_{2\beta} t_r = 1, \qquad t_w = \Psi(n) - q_3 \tag{51c}$$

Obviously, all the propositions about $n-\rho$ in Section B hold here, and hold also for $r-\rho$. The propositions in Section C where applicable also hold. We consolidate these as follows.

PROPOSITION D1: *Neither* $\rho=-1$ *nor* $\omega=0$ *is optimum.*

PROPOSITION D2: *At the optimum,* $l_3>0$ *and max* $(t_r, t_w)>0$.

PROPOSITION D3: *If* $\sigma_2>0$ *(non-forward-rising),* $l_2\neq 0$. *If* $l_2<0$, $t_w>0$. *If* $l_2>0$, $t_w<0$ *and* $t_r>0$. COROLLARY: *If* $l_2 t_w \geq 0$, $\sigma_2<0$.

PROPOSITION D4: *If* $\sigma_2<0$, *then* $t_r>0$ *if* $l_2\geq 0$.

PROPOSITION D5: *If* $l_2<0$ *for all* $\rho<n$, *which implies strong net substitutability, then optimal* $l_2<0$ *and* t_r *may be of either sign. If* $l_2\geq 0$ *for all* $\rho>n$, *because of a strong income effect or weak enough substitutability, then optimal* $t_r>0$ *and* l_2 *of either sign.*

PROPOSITION D6: *If, for every household,* x_0^m *and* x_2^m *are either net complements or independent goods, then* $t_w>0$ *and* $t_r>0$.

III. Concluding Remarks

Less than the usual purpose would be served by a recapitulation of the results obtained in this paper. If our paper is important, it is because of the suggestiveness of the model constructed and the learning experience of analyzing it, not the results finally wrung from it.

The model studied here has some obvious limitations that need no comment: the closedness of the economy to international trade, investment, and migration, the perfectness of the capital market, the fixity of the technology, and the constancy of the population growth rate.

Another limitation is the imposition onto the model of steady-state behavior. Clearly our steady states are only long run. In the immediate present, at the outset of the just era, it cannot generally be supposed that the old wealth owners faced after-tax factor rewards equal to the rewards it will be optimal to offer the young generation—whether or not it is desired to maintain capital and public debt per worker. The kind of steady state studied here is thus to be understood as a rest point to which the system will gravitate once intergeneration justice is in force—at least under basically stationary conditions on the technology and population.

Yet our steady-state formulations are not quite suited to this notion of a just rest point. As a lesson in optimal taxation, the problem posed in Section A is underrestricted—for not *every* steady (k, d) state could be a just rest point. If $b_k(k, d) < 0$ or $b_d(k, d) > 0$, for example, one would work off the excess capital or make up the deficiency in debt. On the other hand, Sections B and C are misrestricted—for neither $b_d(k, d) = 0$ nor $b_k(k, d) = 0$ is an optimal rest point except in the singular Golden Rule case where both equalities hold. And it is perhaps obvious that Section D (the Golden Rule state) is too restrictive in one sense—for intergeneration justice should not be assumed to demand that society from every imaginable initial state should trudge its way to the Golden Rule state.

These propositions (or their analogues) are demonstrated in an as-yet preliminary paper by Phelps and John Riley that studies the dynamics of capital and wealth in an economy (similar to the one here save for homogeneity of the population) programmed for Rawlsian *inter*generational justice. However, in neglecting population heterogeneity that paper omits the matter of *intra*generational justice that is the focus here. Perhaps the union of these two papers will sometime bear fruit in a third paper, that one on taxation for Rawlsian justice within and across generations.

Portfolio Equilibrium and the Balance of Payments: A Monetary Approach

By JACOB A. FRENKEL AND CARLOS A. RODRIGUEZ*

The purpose of this paper is to analyze the adjustment mechanism in a small fully employed economy which trades in commodities, securities, and money. We attempt to shift the analysis from exchange considerations that dominate barter theory to those features that are relevant to intertemporal trade, the accumulation of real and financial assets, and their reflection in the balance of payments. The basic characteristics of the model are the specifications of the production technology, the consumption function, and the portfolio of assets.

The structure of the model and the equilibrium of the closed economy are described in Section I. The effects of opening the economy to international trade are analyzed in Section II, and the dynamics of the open economy, the accumulation of assets and capital are analyzed in Section III. In Section IV we analyze the process by which the economy adjusts to monetary changes. In these sections we distinguish between short-run and long-run effects and explore the exact channels—in terms of the various balance-of-payments accounts—through which the adjustments take place. An analysis of changes in the exchange rate is provided in Section V which concludes the article with some empirically testable hypotheses.

I. The Model of the Closed Economy

Consumption is assumed to depend on the real value of assets a.

$$(1) \qquad c = c(a); \qquad c'(a) > 0$$

The real value of assets in terms of consumption is defined as

$$(2) \qquad a \equiv p_k k + m$$

where k is the stock of capital, $m(=M/P)$ the real value of cash balances, M the nominal stock of money, P the money price of consumption, and p_k the relative price of capital in terms of consumption.

Population (the labor force) is assumed constant and all quantities are measured in per capita terms. Although the model we use is a one-sector model in which output and capital are homogeneous, we follow the standard assumption that capital cannot be dismantled. This, together with the assumption that there are "installation" costs, implies that the price of a machine, or equivalently the price of a title to the ownership of a machine, need not equal the price of a unit of output. The number of units of capital is identically equal to the number of titles of ownership. Households are assumed to own the titles and to rent the machines to firms. Their earnings are the returns on the machines.

Output is assumed to be produced by a linear homogeneous production function so that output per capita can be written as $f(k)$ with the usual restrictions.

The investment function embodies a variant of the Penrose effect (see Hirofumi Uzawa and John Gould). Since the industry is constrained by its managerial ability which is assumed to be constant,

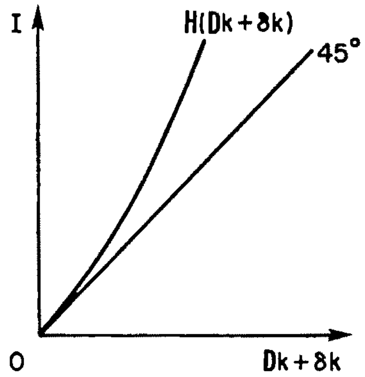

FIGURE 1A

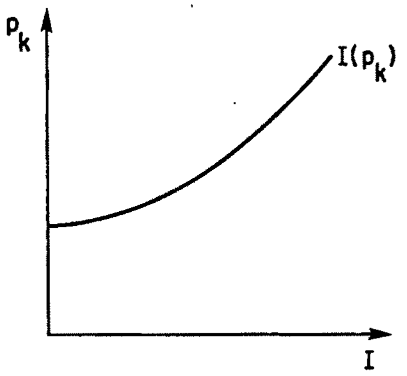

FIGURE 1B

the process of transforming output into nstalled real capital is costly. The adjustnent cost feature of the technology calls or a distinction between investment and gross capital formation. Specifically, deine investment I as the number of units of output that is used in the process of gross capital formation G where $G \equiv Dk + \delta k$, D denotes the operator d/dt, i.e., $Dk \equiv dk/dt$, and δ is the (constant) percentage rate of depreciation. Thus, I can be viewed as the input requirement for gross capital formation. It is assumed that the latter is subject to increasing marginal cost and therefore, that the rate of investnent is related to the rate of gross capital ormation according to

$$I = H(G) \tag{3}$$

where

$$H'(G)>0,\quad H''(G)>0,\quad H(0)=0,\quad H'(0)=1$$

Maximization of profits implies that $p_k = H'(G)$ and therefore the optimal rate of gross capital formation depends on the relative price of capital according to:[1]

$$G \equiv Dk + \delta k = h(p_k) \tag{4}$$

where $h'(p_k) = 1/H''(G) > 0,\ h(1)=0$

Using (4) in (3), results in the rate of investment as a function of p_k:

$$I = H(h(p_k)) = I(p_k) \tag{5}$$

where $I'(p_k) = H'(G)/H''(G) > 0,\ I(1)=0$

Figures 1A and 1B describe equations (3) and (5), respectively. The fundamental aspect that is revealed in these figures is the rising marginal cost (in terms of units of output that are used in the process) of gross capital formation. Note that the same information could be conveyed by replacing Figure 1A with its inverse so as to describe $Dk+\delta k$ as a function of I with diminishing marginal productivity.[2]

---

[1] To derive this relationship, define total output by $Q=F(K,L)$. Output can be used either for consumption or for investment. The firm's revenue is composed of sales of output net of investment and of sales of new equities resulted from net capital formation (p_kDk). Maximization of profits: $F(K,L)-I+p_kDk-wL-rK$ is done subject to $I=H(DK+\delta K)$ where w and r are, respectively, the wage rate and the rental rate (net of capital maintenance) in terms of output. The first-order conditions imply that $p_K=H'(G)$ which results in equation (4) above (see also the Appendix). In order to have a meaningful aggregate of the capital stock, it is assumed that managers (that are in fixed supply for the industry) are mobile among firms so that their rents are equalized across firms.

[2] The production side of the economy could alternatively be described as a two-sector model where the consumption good is produced by a linear homogeneous function of capital and labor and the installed investment good is produced by a linear homogeneous function of the consumption good and of managerial ability. The fundamental element that is required for a determinate demand for investment is diminishing returns in the economy. In the closed economy it is inconsequential whether these diminishing returns are internal to the

The first equilibrium condition is that total output is demanded:

$$(6) \qquad c(a) + I(p_k) = f(k)$$

The second equilibrium condition involves the composition of the portfolio of assets. The desired ratio l of real cash balances to the real value of capital (equities) is assumed to depend on the rate of interest ρ:

$$(7) \qquad m = l(\rho)p_k k \qquad l'(\rho) < 0$$

where the rate of interest is identified with the net rate of return on capital:[3]

$$(8) \qquad \rho = \frac{f'(k)}{p_k} - \delta$$

In equilibrium output is demanded (flow equilibrium (6)), and the actual stocks of assets are held in the desired proportion (stock equilibrium (7)). Short-run equilibrium requires that conditions (6)–(7) are met at each instant. Since at any instant the stocks of capital k and nominal balances M are given, equilibrium in the short run determines the money price of output P and the relative price of capital p_k (and thereby the rate of interest ρ). The effect of changes in the stock of capital on the price of capital (and thus on the rate of interest) can be ascertained by solving for p_k as a function of k from the short-run equilibrium conditions (6)–(7). From (4) the evolution of the capital stock is described by

$$(9) \qquad Dk = h(p_k) - \delta k$$

and in the steady state net capital formation is zero ($Dk=0$) and gross investment is just sufficient to replace the depreciation of capital.

Assume that the closed economy converged to its steady state and denote by $\bar{k}$ and $\bar{p}_k$ the steady-state values of the closed economy stock of capital and price of capital.[4] Associated with the steady-state values of $\bar{k}$ and $\bar{p}_k$ there is (from (8)) the steady-state rate of interest $\bar{\rho}$ and (from (7)) the steady-state value of real balances $\bar{m}$. Given the nominal money stock $\overline{M}$, the steady-state price level is $\overline{P}$.

II. Opening to International Trade

Suppose now that the economy is at the steady state, and is opened to international trade in both securities and goods. Suppose that the economy is small relative to the rest of the world so that it faces a given world money price of goods P^* and a given world rate of interest ρ^*. Without loss of generality it is assumed that $\rho^* < \bar{\rho}$.

To accommodate the analysis of the open economy under a pegged exchange rate, the closed economy model in the preceding section must be modified in some respects. First the authorities must determine the relative price of the foreign currency in terms of the domestic currency (the exchange rate). It is assumed that upon the opening to trade, the exchange rate e is set according to the purchasing power parity so that

$$(10) \qquad e = \overline{P}/P^*$$

---

firm or arise from the idiosyncracy of production processes; in the open economy a discrepancy is possible between the production and installation of capital goods, and thus a determinate demand for each activity cannot be derived from the standard two-sector model. An alternative derivation of the demand for investment is provided by Stanley Fischer and Frenkel (1972).

[3] We assume that expectations are static and thus we do not allow for anticipated capital gains or losses on equity holdings. Similarly, we assume that the expected rate of inflation is zero and thus we do not distinguish between the real and the nominal rates of interest. Since when the small economy is open it is assumed to face a fixed world price level, we prefer, for the sake of simplicity, not to complicate the structure of the closed economy model by incorporating inflationary expectations. We have analyzed the dynamics of inflation in a similar closed economy model in our 1975a paper.

[4] It can be shown that both the capital stock and its relative price approach the steady state monotonically. The system must be stable if a rise in the stock of capital lowers its price. If, however, a rise in the capital stock induces a rise in its price, the system may still be stable if the rate of depreciation δ is high.

and thus the price of goods in terms of domestic currency remains unchanged when trade opens. Second, we have to distinguish between the location of the stock of capital which determines production and the ownership of capital which determines consumption and portfolio choice. The home country's ownership of capital is denoted by k_D and we continue to denote the stock of capital that is located in the home country by k. If k differs from k_D, foreign ownership (or debt) makes up for the difference. For example, if k were to exceed k_D, foreigners own k_F units of domestically located capital where

$$k_F \equiv k - k_D \tag{11}$$

When the home country is a net debtor ($k_F > 0$), it is assumed that it does not own any foreign equities and when it is a net creditor ($k_F < 0$), it owns the entire domestic capital stock plus $k_D - k$ units of foreign equities. Accordingly, the definition of domestically owned assets becomes

$$a \equiv p_k k_D + m \tag{2'}$$

and the liquidity preference function becomes

$$m = l(\rho) p_k k_D \tag{7'}$$

Short-run equilibrium of the open small economy requires that the money price of goods in terms of each currency is equalized (equation (10)) and that the domestic rate of interest equals the world rate. The latter condition implies that

$$\rho = \frac{f'(k)}{p_k} - \delta = \rho^* \tag{12}$$

Thus, upon the opening to trade (with $k = \bar{k}$), the domestic price of capital rises to p_k' (as a result of the excess demand for domestic securities) so that $[f'(\bar{k})/p_k'] - \delta = \rho^*$. Thus, the opening to trade results in a capital gain on the ownership of domestic capital and consequently in a higher value of assets.[5] The decline in the rate of interest raises the desired ratio of real balances to capital (equities) which in turn induces an instantaneous adjustment of the portfolio. These adjustments are shown in Figure 2 where the pretrade equilibrium is at point A, the initial holdings of capital and real cash balances are $\bar{k}$ and $\bar{m}$, respectively, the real value of assets is $\bar{a} = \bar{m} + \bar{p}_k \bar{k}$, and the pretrade price of capital is $\bar{p}_k$. Upon the opening of trade the rate of interest falls to ρ^*, the price of capital rises to p_k', and the value of assets rises to $a' = \bar{m} + p_k' \bar{k}$. Given the lower rate of interest and the higher value of assets, short-run equilibrium is attained at point B (the intersection of the liquidity preference schedule (7') with the new asset constraint), and the holdings of equities and real cash balances are changed to k_D' and m', respectively. Accordingly, upon the opening to trade the economy exchanges with the rest of the world $\bar{k} - k_D'$ units of equities for $m' - \bar{m}$ units of real cash balances as portfolio equilibrium moves instantaneously from point A to point B.

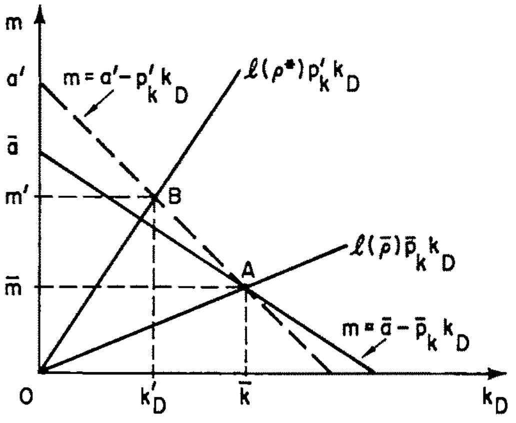

FIGURE 2

---

[5] The effects of these capital gains on the gains from trade in a two-country model are analyzed in Fischer and Frenkel (1974).

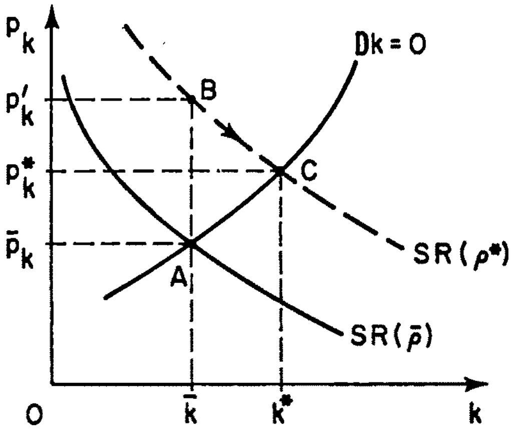

FIGURE 3

III. Dynamics of the Open Economy

The higher price of capital increases the profitability of investment and thus results in a higher equilibrium steady-state capital stock. The dynamics of the capital stock and of the price of capital are described in Figure 3. The locus of short-run equilibria SR describes combinations of p_k and k which maintain a constant rate of interest[6] (a lower rate of interest corresponds to a higher locus in Figure 3). The $(Dk=0)$ locus is derived from equation (9) and describes combinations of p_k and k for which the capital stock remains constant. Its slope is positive since from (4) a higher price of capital increases profitability of gross capital formation while a higher stock of capital increases the depreciation requirement.

Upon the opening to trade, short-run equilibrium moves from point A to point B as the price of capital rises to p'_k. At point B, $Dk>0$ and the system moves monotonically along the $SR(\rho^*)$ schedule towards the new steady state (point C) at which $k=k^*$ and $p_k=p^*_k$. As can be seen, the new steady-state price of capital must exceed $\bar{p}_k$ so as to induce the larger gross investment that is required to just replace the depreciation on the higher stock of capital.

Since consumption depends on the value of assets, we need to analyze the dynamics of assets in order to characterize the evolution of the economy through time. We turn now to the dynamics of the value of assets and then proceed to analyze the dynamics of the balance of payments and its components.

The rate of change in the value of assets is comprised of planned additions to assets (planned savings) and of capital gains and can be written as:

$$Da = [f(k) + p_k Dk - I(p_k) - \rho^* p_k k_F - c(a)] + k_D Dp_k \tag{13}$$

The interpretation of (13) is as follows: The first three terms on the right-hand side of (13) correspond to net *domestic* product (*NDP*) while the first four terms include international dividend payments and correspond to net *national* product (*NNP*). The bracketed term corresponds, therefore, to *ex ante* savings. The *actual* change in the value of assets Da, is an *ex post* concept which corresponds to the sum of *ex ante* savings plus capital gains on equity holdings $(k_D Dp_k)$.[7]

Since all the variables in (13) depend on k and a alone,[8] we can write the dynamic equations for the capital stock and the value of assets as

$$Dk = Dk(k) \tag{9'}$$

$$Da = Da(k, a) \tag{13'}$$

It is shown in the Appendix that around

---

[6] From (8), the equation of the SR locus is $p_k=f'(k)/(\rho+\delta)$ and its slope is $(dp_k/dK)_{SR}=f''/(\rho+\delta)<0$.

[7] This distinction between intended and actual savings presumes that all unanticipated capital gains are absorbed in asset accumulation while all desired consumption plans are fulfilled.

[8] From (2) and (7) $k_D=a/[p_k(1+l)]$; from (11) $k_F=k-k_D$ and from (9) Dk depends on p_k and k. From (12)—given the rate of interest—p_k depends only on k (see fn. 6) and therefore $Dp_k=[f''(k)/(\rho+\delta)]Dk$. Thus all variables in (13) depend on k and a alone.

the steady state, $\partial Da/\partial k > 0$.[9] Since $\partial Dk/\partial k < 0$, stability requires that around the steady state $\partial Da/\partial a < 0$. Intuitively, the rise in the value of assets raises consumption according to the consumption function, and raises income by the yield on the additional assets; the stability condition assures that the induced rise in consumption exceeds the additional yield on assets so as to prevent a further asset accumulation.

The dynamics of the capital stock and the value of assets following the opening to trade are analyzed in Figure 4. Combinations of k and a for which k and a are constant are shown by the $(Dk = 0)$ and the $(Da = 0)$ loci, respectively. The slopes of these loci (around the stable steady state) are determined by (9′) and (13′), and the arrows in Figure 4 correspond to the signs of the partial derivatives. Upon the opening to trade the capital stock is $\bar{k}$ and since $\rho^* < \bar{\rho}$, the new steady-state capital stock must exceed $\bar{k}$ and thus the $(Dk = 0)$ locus must be to the right of $\bar{k}$. The initial value of assets immediately after trade opens depends on the extent of the capital gain that is induced by the rise in the price of capital. In fact the rise in the value of assets may raise consumption by an amount that is sufficient to cause dissavings as shown in the path starting from B in Figure 4. Depending on the extent of the capital gain, the initial point might be above the $(Da = 0)$ locus in which case initially $Da < 0$ as in points B and B', or it might be below the $(Da = 0)$ locus in which case $Da > 0$ as in point B''. Whatever is the actual path, the economy converges eventually towards the new steady state (point C in Figure 4) in which k^* and a^* are the open economy's steady-state values of capital and assets.

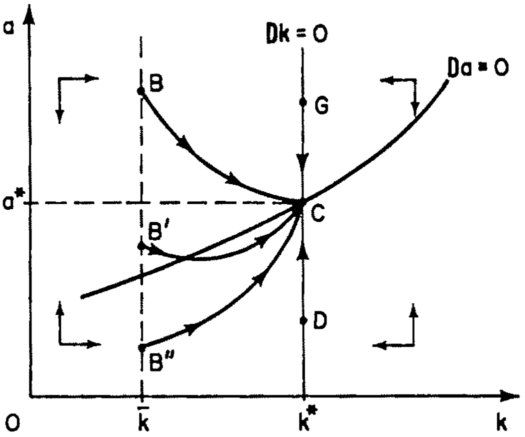

FIGURE 4

The surplus in the balance of trade b_T is defined as the excess of domestic output over absorption (consumption plus investment):

$$(14) \qquad b_T \equiv f(k) - c(a) - I(p_k)$$

The budget constraint implies that the overall surplus in the balance of payments Dm equals the sum of the surpluses in the trade account b_T, the service account $(b_S = -\rho^* p_k k_F)$, and the capital account $(b_C = p_k D k_F)$:[10]

$$(15) \qquad b_T = Dm + \rho^* p_k k_F - p_k D k_F$$

The surplus in the current account corresponds to the excess of income over expenditures, i.e., to the accumulation of assets. Under the assumption that the economy is not growing, the steady-state value of assets is fixed and thus the current account is balanced $(b_T + b_S = 0)$. Since the current account is balanced, the surplus in the capital account b_C must equal the overall surplus in the balance of payments Dm. In the absence of autonomous domestic credit creation, both the capital account and the overall surplus in the balance of payments are zero. Whether the steady-state service account is in surplus or in deficit depends on the balance of indebtedness, i.e., on whether the economy is a net creditor or a net debtor. This cannot be determined on a priori grounds since it depends on two independent considerations—that of savings and that of investment. If the cumulative acquisition of equities k_D exceeds the cumulative supply of domestic equities k^*, then the economy is a net creditor and the steady-state service account is in surplus, and conversely when k_D falls short of k^*.

---

[9] An intuitive explanation for that sign is as follows: a rise in the capital stock (holding assets constant) raises k_F and does not raise disposable income since around the steady state the capital stock is at its optimal level and the rise in output is just sufficient to service the larger debt. Consequently, planned savings do not change and the only effect on the rate of change in the value of assets arises from capital gains. Since around the steady state $\partial Dp_k/\partial k = [f''(k)/(\rho+\delta)]\partial Dk/\partial k > 0$, it follows that $\partial Da/\partial k > 0$.

[10] For a similar framework for the analysis of the balance of payments accounts see Rudiger Dornbusch (1971, 1975), Frenkel (1971, 1975a), Frenkel and Fischer, Ryutaro Komiya, and Douglas Purvis.

IV. The Adjustments to Monetary Changes

Consider a once and for all change in the monetary stock which is brought about by an unanticipated governmental transfer. Given the exchange rate, money prices are given and therefore changes in the nominal stock of cash balances correspond to changes in the real stock. Suppose that at time t_0 the real stock of cash balances is raised by dm_0.[11] The impact effect of this change is to raise the value of assets from a^* to a^*+dm_0 and thus (given the rate of interest) to induce an excess demand for equities that is equal in value to $p_k^* dk_D = dm_0/(1+l)$. Accordingly, instantaneous portfolio adjustment results in an immediate exchange of part of the increased monetary stock for equities resulting therefore in larger holdings of both real cash balances and equities.

Figure 5 describes the impact effect of this change where initial equilibrium is at point A and the new instantaneous equilibrium is attained at point B with equilibrium holdings of real cash balances that are higher by $dm = dm_0 - dm_0/(1+l)$.

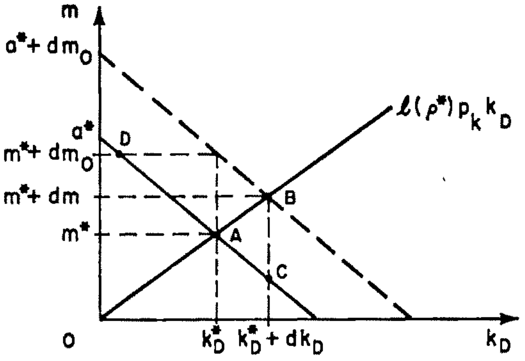

FIGURE 5

In terms of Figure 4 the impact effect is described by moving the economy from point C to point G along the $(Dk=0)$ locus. Therefore, starting at point G, the dynamics of the adjustment is characterized by a continuous reduction in assets until the original steady state is attained at point C in Figure 4. Since the monetary change does not affect the stock of capital and its price, it does not affect the optimal rate of capital formation and thus the path of adjustment must be along the $(Dk=0)$ locus. It follows that along the path the capital stock and the price of capital remain constant at their previous levels k^* and p_k^*.

The instantaneous adjustment of the portfolio as well as the transition to the new steady state are effected through the various accounts of the balance of payments. Since the monetary change does not affect the capital stock, the level of output is fixed and consumption rises. Therefore, the impact effect on the balance of trade is to lower the surplus (or raise the deficit) by $(\partial c/\partial a)dm_0$. The instantaneous adjustment in the portfolio of assets involves an exchange of a fraction $1/(1+l)$ of the increased money stock for securities. This exchange improves the balance of indebtedness and causes an improvement in

---

[11] In fact, the exogenous change in the nominal money stock is dM_0; however, since the price level is given, this change in the nominal stock corresponds to a change in the real stock by dm_0.

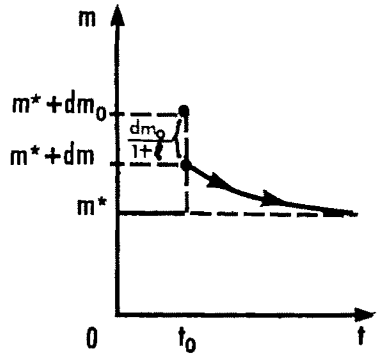

FIGURE 6A

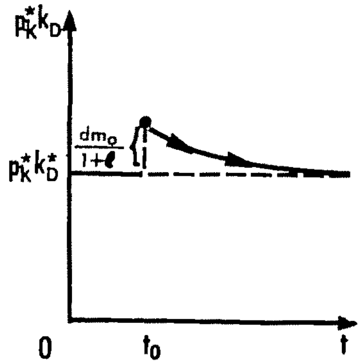

FIGURE 6B

the service account by $\rho^* dm_0/(1+l)$. The sum of the impact effects on the balance of trade and on the service account is the impact effect on the current account, i.e., on asset accumulation. When the system is stable, $\partial Da/\partial a = -\partial c/\partial a + \rho^*/(1+l) < 0$, and therefore the impact effect is to induce instantaneous asset decumulation at the rate $(\partial Da/\partial a)dm_0$. This desired asset decumulation will be divided between securities and money so as to maintain portfolio balance. Consequently, *aside from the initial stock adjustment*,[12] the impact effects will be a surplus of $-(\partial Da/\partial a)dm_0/(1+l)$ in the capital account and a deficit of $l(\partial Da/\partial a)dm_0/(1+l)$ in the overall balance of payments.

So far we have examined the impact effects of the monetary change. Accordingly, the effects on the various accounts of the balance of payments were confined to the new instantaneous short-run equilibrium when the economy is at point G in Figure 4 and at point B in Figure 5. We turn now to the analysis of the paths of the various accounts in the transition to the steady state.

When the value of assets exceeds the steady-state value, individuals run down their holdings of both equities and real cash balances and thus induce a surplus in the capital account and a deficit in the monetary account (the overall balance of payments). The stock of assets changes through time according to $(\partial Da/\partial a)Da < 0$ and this path corresponds to the path of the current account $Db_T + Db_S$. Since during the adjustment period assets decline, consumption falls and the balance of trade improves. On the other hand, since along the path the economy is exporting securities, its indebtedness increases through time by $Da/(1+l)$ and thereby, the service account deteriorates by $\rho^* Da/(1+l)$. The surplus in the capital account and the deficit in the overall balance of payments are proportional to Da and decline through time. The process comes to an end when the initial asset position is restored and $Da = 0$.

The paths of the stocks of money and ownership of equities are described in Figure 6, while Figure 7 summarizes the

---

[12] Since our analysis is conducted in terms of continuous time, the algebraic formulation of the exact paths is complicated due to the fact that there are both adjustments that occur through time and adjustments that occur instantaneously in attaining a continuous portfolio balance. We have defined the capital account and the overall balance of payments in terms of the changes in the holdings of securities and money ($p_k Dk_F$ and Dm) that occur *through time*; therefore, these definitions do not capture international transactions that occur discretely as those that are involved in the instantaneous exchange of $dm_0/(1+l)$ of cash balances for equities. Since empirical data are reported discretely, this transaction will be reported as a deficit in the overall balance of payments and an equal deficit in the recorded capital account. The following expressions that pertain to the impact effect do not include these initial stock adjustments and correspond therefore to the situation at point B in Figure 5.

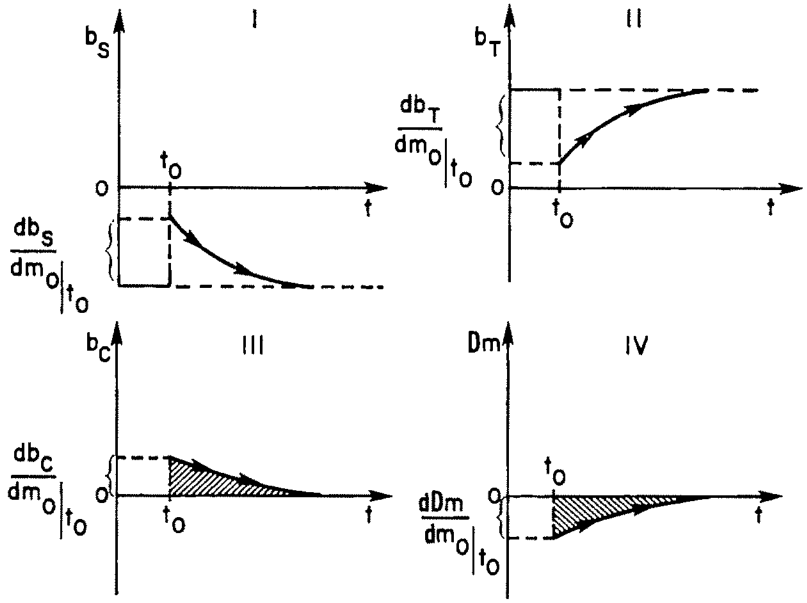

FIGURE 7

dynamics of the various balance of payments accounts following the once and for all rise in the monetary stock.

In terms of Figure 5, the transition toward the steady state is characterized by a movement from B to A along the portfolio balance locus. Since during the transition period portfolio equilibrium obtains, it follows that the percentage rate of change in the monetary stock must equal the percentage rate of change in the holdings of equities. Therefore at each point of time along the path (following the initial restoration of portfolio balance), the ratio of the deficit in the overall balance of payments to the surplus in the capital account must be l.

The adjustment period continues as long as the value of assets exceeds a^*. The cumulative deficit in the overall balance of payments is the shaded area in Panel IV of Figure 7 and is equal to the initial rise in the equilibrium holdings of money $[dm_0 - dm_0/(1+l)]$. Likewise, the cumulative surplus in the capital account is the shaded area in Panel III of Figure 7 and is equal to the initial rise in the value of the equilibrium holdings of equities $[dm_0/(1+l)]$. The sum of the two shaded areas is the initial rise in the quantity of money dm_0 and the ratio of the two areas is equal to the desired ratio of money to equities l.

To summarize, changes in the quantity of money which are brought about by a transfer do not affect the long-run equilibrium of the system—a result which is common to the literature on the monetary approach to the balance of payments.[13] The adjustment to such monetary changes takes two forms. First, there is an instantaneous adjustment in the portfolio of assets in which part of the increased stock of money is immediately exported in exchange for equities. Second, there is a period of adjustment during which the economy runs down assets.[14] These adjustments are reflected in the various accounts of the balance of payments and the balance of indebtedness.

---

[13] For a collection of contributions to this literature, see Frenkel and Harry Johnson. See also Frenkel (1975b).

[14] A similar distinction between the instantaneous part and the time-dependent part of the adjustment process is emphasized by Dornbusch (1975a), Michael Mussa, and Purvis.

Consider next the effects of changes in the quantity of money which are brought about through open market operations in equities. When the government owns part of the capital stock k_G, equation (11) becomes

$$k = k_D + k_G + k_F \tag{11'}$$

When the quantity of money is raised by dm_0 through an open market purchase then

$$dm_0 = \overset{*}{p_k} dk_G = - \overset{*}{p_k} dk_D \tag{16}$$

The effects of these operations depend on the manner by which the government disposes of the returns from their holdings of securities as well as on the manner by which the private sector treats these governmental actions. It is assumed that the returns on governmental holdings of equities are returned to the public as transfers or tax rebates.

In analyzing the reaction of the private sector to the open market purchase, it is useful to consider two extreme cases. Assume first that the private sector does not capitalize the flow of transfers. In this case an open market purchase does not affect the wealth position of individual asset holders, but it raises the ratio of real balances to equities above the desired ratio l. In terms of Figure 5, it moves the current holdings of assets from point A to point D. Since the rate of interest is given, individuals will restore portfolio equilibrium instantaneously (to point A) by exchanging the increased stock of cash balances for foreign securities and thus reducing the economy's net debtor position by $p_k^* dk_F = dm_0$. In other words, the fact that the open market operation is conducted in assets that are traded internationally at a given price enables the private sector to nullify the actions of the monetary authority. In fact, in this case open market operations amount to an exchange of foreign exchange reserves for securities between the monetary authorities and foreign asset holders.[15] Since the economy's net debtor position declines by $p_k^* dk_F$, the instantaneous deficit in the service account must also decline by $\rho^* p_k^* dk_F$. However, since $k_F = k - k_G - a / [p_k^*(1+l)]$, it follows from (13) that an open market purchase shifts the $(Da=0)$ locus upwards to a point like G in Figure 4. Along the path to the new long-run equilibrium the economy imports assets (securities and money), the service account improves, and the balance of trade deteriorates. Long-run equilibrium is reached when the increased value of assets induces higher consumption at a rate that is equal to $\rho^* p_k^* dk_G$, the noncapitalized governmental transfer.

Consider next the other extreme case where the private sector anticipates and capitalizes the flow of transfers $\rho^* p_k^* dk_G$, and assumes that these claims are marketable like any other equity. Effectively therefore, the private sector conceives of the equities that are held by the government as its own equities that are deposited in the governmental safekeeping box. Accordingly, the wealth of the private sector is $a = p_k^*(k_D + k_G) + m$ and the liquidity preference function is $m = l(\rho^*) p_k^*(k_D + k_G)$. An open-market purchase in this case does not affect the sum $(k_D + k_G)$, but it raises the monetary stock by dm_0. Consequently, the effects of an open-market purchase are identical to the effects of an increase in the monetary stock that is brought about through an unanticipated governmental transfer of cash balances.

The analysis of the two extreme cases

---

[15] These implications are elaborated by Robert Mundell (1968, 1971), Ronald McKinnon, Johnson (1972), and Dornbusch (1974, 1975a).

reveals that the differences between the effects of open-market operations and the effects of unanticipated transfers of cash balances stem from issues that are related to the degrees of capitalization and marketability of claims to future income streams.[16]

The effects of changes in the liquidity preference can be easily analyzed by including a shift parameter in the liquidity preference function (7′) and by exploring the exact channels—in terms of the various balance-of-payments accounts—through which adjustment takes place. It can be shown that a rise in the desired ratio of money to equities has no effect on the stock of capital and on its price, while it results in lower long-run holdings of assets. Following the initial stock adjustment (which involves an instantaneous sale of equities for money), the economy gradually runs down assets. The cumulative deficit in the balance of payments may exceed or fall short of the initial instantaneous rise in the monetary stock. In other words, the long-run effects on the holdings of real balances are ambiguous.

V. The Effects of Changes in the Exchange Rate

To analyze changes in the exchange rate recall that the real quantity of cash balances is $m = M/eP^*$. Since the money price of goods in terms of foreign currency is given, it follows that the analysis of changes in the exchange rate is identical to the analysis of changes in the nominal quantity of money. In fact, a devaluation of the currency is exactly an imposition of a capital levy on real cash balances, and therefore the analysis in the previous section (in which the quantity of money was raised through an unanticipated transfer) is identical to the analysis of a revaluation of the currency, while the analogue to a devaluation of the currency is a reduction of the nominal quantity of money. This correspondence is implied by the fact that the system is homogeneous of degree zero in the nominal money stock M and in the exchange rate e. In line with the literature on the monetary approach to the balance of payments, a devaluation must improve the balance of payments whenever it induces an excess demand for money.[17] The additional insight provided by the present analysis is in identifying the exact channels—in terms of the various balance-of-payments accounts—through which the adjustment takes place. The distinction between the impact effect and the transition period emphasizes the role of the portfolio of assets in enabling the private sector to build up instantaneously part of the depreciated real monetary stock. The analysis of devaluation can be shown in terms of Figure 5. Consider an initial long-run equilibrium at point B. A devaluation of the currency lowers the real value of cash balances to point C. An instantaneous adjustment of the portfolio enables the private sector to exchange securities for cash balances and to arrive at point A, and thus to build up immediately part of the depreciated monetary stock. The rest of the adjustment is carried out through time as the community reduces expenditures relative to income and thereby runs a balance of trade surplus. The accumulation of assets along the path between point A and point B is reflected in a deficit in the capital account and a surplus in the overall balance of payments.[18] The process of adjustment is completed once the nominal stock of money has risen equiproportionally to the depreciation of the currency.

---

[16] These issues are analyzed in the context of a closed economy by Lloyd Metzler and Mundell (1971, ch. 1).

[17] See Eitan Berglas, Dornbusch (1973), Johnson (1972, 1975), Mundell (1971), Mussa, and Johan Myhrman.

[18] Similarly, in terms of Figure 4 a devaluation lowers the value of assets from point C to point D and the adjustment is described by the path DC. Since the yield on equities is given by the world market, the capital stock remains constant during the transition and the path of adjustment lies along the $(Dk=0)$ locus. Dornbusch (1975a) has analyzed the effects of devaluation in

In summary, the above analysis of devaluation provides some testable hypotheses:

(i) The *initial* effects of a devaluation should induce a surplus in the capital account, an improvement in the trade account, a deterioration in the debt service account, and a surplus in the monetary account. In the main, the monetary account and the capital account reflect the once and for all *stock* adjustment that is required to restore portfolio balance and in the short run most of the adjustment is effected through these assets accounts.

(ii) During the later phases of the adjustment process, the gradual accumulation of assets is reflected in a deficit in the capital account and a surplus in the monetary account, both of which decline through time as the adjustment process comes close to an end. During these phases the trade account deteriorates while the debt service account improves.[19]

(iii) Since along the path of adjustment portfolio equilibrium obtains, we expect that during the later phases the ratio of the surplus in the monetary account to the deficit in the capital account should approximate the desired composition ratio l.[20]

(iv) Although the devaluation per se does not induce changes in the rate of capital formation, the adjustment process involves changes in net ownership of foreign securities. Consequently we expect that following a change in the exchange rate, the path of *GNP* will display larger variations than the path of gross domestic product (*GDP*).

The model also reveals that if the exchange rate were flexible, then a doubling of the nominal money stock would result in an equiproportionate change in the exchange rate. In other words, the fact that the system is homogeneous of degree zero in M and e implies a symmetry between the pegged and the flexible exchange rate systems. Under a pegged exchange rate system a devaluation of the currency results, in the long run, in an equiproportionate rise in the nominal stock of money, while under a flexible exchange rate system a doubling of the nominal stock of money results in an equiproportionate depreciation of the currency. In both cases, there are no long-run changes in the real value of cash balances as well as in all other real quantities—although of course a devaluation of the currency raises the real stock of international reserves when the exchange rate is pegged.

Although the long-run effects are symmetric under the two exchange rate sys-

---

a model which includes internationally traded bonds in addition to equities that are nontraded assets and therefore their yield is determined endogenously. In such a model a devaluation (from an equilibrium position) induces a transitory cycle of the capital stock.

[19] It is of interest to note that in a recent paper, using a different model, Dennis Logue and Thomas Willett applied a portfolio approach to the analysis of exchange rate changes and conclude that ". . . portfolio rebalancing generally suggests therefore that a devaluation will lead to capital inflow . . . as investors adjust their portfolio to take account of the wealth effects of an exchange rate realignment." This conclusion is in full conformity with our analysis of the *initial* phase of the adjustment—the phase in which desired portfolio *composition* is restored. However, the desired *size* of the portfolio is attained in later phases during which the capital account is in a deficit. Moreover, Logue and Willett assume that the ". . . adjusting country pursues a monetary-fiscal policy mix which leaves aggregate demand unaltered." Our analysis shows that when such policies are not followed, individuals reduce expenditures relative to income in an attempt to rebuild their depreciated stock of assets, and thereby induce an improvement in the trade account.

[20] Strictly speaking, these hypotheses are confined to the case in which the monetary authorities maintain a rigid ratio between the stock of money and international reserves and do not pursue independent credit and sterilization policies. The hypotheses can be easily modified to accommodate the case in which the composition ratio of the Central Bank's assets does change. For a framework for the analysis of the effects of changes in the composition ratio, see Johnson (1972).

tems, the adjustment process is not. When the exchange rate is pegged the recuperation of cash balances following a devaluation is gradual and is effected through time as the community runs a surplus in the balance of payments. When the exchange rate is flexible, the restoration of the equilibrium value of real cash balances following a rise in the nominal stock of money is instantaneous and the exchange rate depreciates immediately at the instant of the monetary change. This latter phenomenon emphasizes the fact that the exchange rate, being the relative price of monies, is determined in a similar way as other relative asset prices and thus the equilibrium exchange rate is that relative price of monies at which the existing stocks are willingly held.[21]

APPENDIX

In this Appendix we derive equation (13′) in the text and derive the signs of its partial derivatives. In deriving the optimal behavior of the firm it is convenient to define quasi profits π as the return to labor plus rents to entrepreneurs. The firm's revenue is composed of sales of output that are not invested $[f(k)-H(Dk+\delta k)]$ and of sales of new equities (p_kDk). Its interest cost on capital is $\rho p_k k$. Thus π is:[22]

$$\text{(A1)} \qquad \pi = f(k) - H(Dk + \delta k) + p_k Dk - \rho p_k k$$

The firm, assuming that p_k is fixed, attains the rate of net capital formation such that

$$\text{(A2)} \qquad \frac{\partial \pi}{\partial Dk} = - H'(Dk + \delta k) + p_k = 0$$

thus,

$$\text{(A3)} \qquad Dk = h(p_k) - \delta k$$

The choice of the optimal capital intensity for the representative firm satisfies (A4):[23]

$$\text{(A4)} \qquad \frac{\partial \pi}{\partial k} = f'(k) - \delta H'(Dk + \delta k) - \rho p_k = 0$$

and using (A2), (A4) becomes

$$\text{(A4}'\text{)} \qquad p_k = \frac{f'(k)}{\rho + \delta} = p_k(k); \qquad \partial p_k/\partial k < 0$$

Using (A4′) in (A3) yields

$$\text{(A3}'\text{)} \qquad Dk = Dk(k); \qquad \partial Dk/\partial k < 0$$

From (A4′) Dp_k can be written as

$$\text{(A5)} \qquad Dp_k = \frac{f''(k)}{\rho + \delta} Dk$$

and using (A3′) yields

$$\text{(A5}'\text{)} \quad Dp_k = \frac{f''(k)}{\rho + \delta} Dk(k) = Dp_k(k)$$

When (A5′) is evaluated around the steady state (with $Dk=0$),

$$\text{(A6)} \qquad \left. \frac{\partial Dp_k}{\partial k} \right|_{Dk=0} = \frac{f''(k)}{\rho + \delta} \frac{\partial Dk}{\partial k} > 0$$

The rate of change in the value of assets can be written (using (13) in the text) as

$$\text{(A7)} \quad Da = \bar{\pi}(k) + \rho^* p_k k_D - c(a) + k_D Dp_k$$

where $\bar{\pi}(k)$ is equation (A1) above, incorporating (from (A4′)) the negative dependence of p_k on k which is ignored by the competitive firm. But since $p_k k_D = a/(1+l)$, we have,

---

[21] This view on the role and determination of the rate of exchange is in sharp contrast with the popular notion that the exchange rate is determined in the flow market so as to assure a balanced balance of payments. The role of stocks rather than flows in exchange rate theory was recognized in some early writings but ignored to a large extent in more recent approaches. The revival of the asset view is a natural application of the monetary approach to the balance of payments; see for example Dornbusch (1975b).

[22] Alternatively (A1) could be written in the form

$$\text{(A1}'\text{)} \qquad \pi = f(k) - H(Dk+\delta k) + p_k(Dk+\delta k) - p_k(\rho+\delta)k$$

where the last term corresponds to the concept of "user cost." Obviously (A1′) is identical to (A1), and therefore reflects the fact the real cost of using capital (and thus optimal use) is independent of contractual arrangements regarding capital maintenance.

[23] Note that to the extent that we assume that capital is specific at the level of the firm, (A4) might be viewed as the condition for optimal allocation of labor among firms. We are indebted to Robert Lucas, Jr. and Hiroyuki Hino for useful discussion on these issues.

using (A5′),

$$\text{(A7}'\text{)}\quad Da = \tilde{\pi}(k) + \frac{\rho^*}{1+l}a - c(a) + \frac{a}{1+l}\,\frac{Dp_k(k)}{p_k(k)}$$

that is,

$$\text{(A8)}\qquad Da = Da(k, a)$$

which is equation (13′) in the text.

We wish to evaluate $\partial Da/\partial k$ and $\partial Da/\partial a$ around the steady state (where $Dk = Dp_k = 0$). From (A7′),

$$\text{(A9)}\quad \frac{\partial Da}{\partial k} = \frac{\partial \tilde{\pi}}{\partial k} + \frac{a}{p_k(1+l)}\,\frac{\partial Dp_k}{\partial k}$$

But since around the steady state the competitive firm equates the marginal productivity of capital $f'(k)$ with user cost $(\rho^*+\delta)p_k$, $\partial\tilde{\pi}/\partial k = -\rho^* k\partial p_k/\partial k > 0$, and the only source for changes in the rate of change of the value of assets is capital gains. Using (A4′) and (A6) in (A9) yields:

$$\text{(A9}'\text{)}\quad \frac{\partial Da}{\partial k} = \left[\frac{a}{p_k(1+l)}\,\frac{\partial Dk}{\partial k} - \rho^* k\right] \cdot \frac{f''}{\rho^*+\delta} > 0$$

From (A7′), around the steady state

$$\text{(A10)}\qquad \frac{\partial Da}{\partial a} = \frac{\rho^*}{1+l} - \frac{\partial c}{\partial a}$$

The rise in the value of assets increases interest earnings by $\rho^* p_k \partial k_D/\partial a = \rho^*/(1+l)$. A rise in assets, in turn, raises consumption by $\partial c/\partial a$, and therefore, stability requires that $\partial c/\partial a > \rho^*/(1+l)$ so as to prevent a further accumulation of assets. Thus, stability requires that $\partial Da/\partial a < 0$.

Profit Maximization and Alternative Theories: A Dynamic Reconciliation

By Robert E. Wong*

For a number of decades now the classical concept of the profit-maximizing firm has come under attack. The first major assault may have been the findings of the study by Robert Hall and Charles Hitch in 1939. Their results indicated little support for the use of marginal principles in the real world of business. Their conclusions questioned the validity of the profit-maximizing model of the firm. Since that time a number of alternative theories have emerged with regard to firm objectives and behavior. Probably the most frequently discussed alternative is the sales maximization objective proposed by William Baumol. Baumol's observations as a consultant to business indicated that firms will maximize revenues or sales subject to a constraint of some satisfactory level of profits. J. R. Wilson considers the possibility of dividend maximization by the stockholder controlled firms and undistributed profits maximization by management controlled firms. Armen Alchian and William Allen consider the concept of wealth maximization which essentially corresponds to the maximization of the present value of discounted net income, net receipts, or net cash flow considered by George Stigler, Dale Jorgenson, and Kenneth Arrow. These latter concepts are based upon the streams of returns to the entrepreneur. There has also been a development of a behavioral theory of the firm by Richard Cyert and James March in which individual managerial goals may exist and are not consistent with the organizational goals of profit maximization.

The purpose of this paper is to show that profit maximization and the alternative referenced theories with the exception of the behavioral theory can be reconciled with a dynamic analysis of a firm. The different types of maximizing behavior referenced can be shown to be a part of the expected behavior of the firm operating to maximize the present value of its dividend stream. To perform the reconciliation, a modified Jorgenson dynamic model will be employed. It should be noted that the reconciliation of various maximization concepts with a dynamic analysis was implied in the analysis by Gerald Nordquist.

I. Objective of the Firm

The owners of the corporate form of business are the stockholders. A successful corporation generally will never liquidate its assets, and therefore the stockholder cannot expect that his share of the net worth of the firm will ever be distributed. Thus, the value of his stock is based upon dividends which he receives and expects to receive. In theory the stock value is the discounted stream of dividends of the corporation through an infinite time period. The stockholders would want to maximize their stock value and should direct the activities of the firm's management to do this. We may write the objective as

$$V = \int_0^\infty De^{-rt}dt \tag{1}$$

where D = dividends, r = discount rate, and V = present stock value. The dividend paid to the stockholders is distributed out of net receipts which are defined here as the difference of revenues and expenses in production over a unit of time. The expenses consist only of wages to labor.

That portion of net receipts not distributed to dividends is used for investment in capital. Capital is assumed to be depreciating at a constant rate. The rate of change of capital can be written as

---

* Economist, department of savings and loan, State of California and senior lecturer, University of Southern California. I wish to thank Michael Intriligator, William Barger, and a referee for their helpful comments.

$$(2)\qquad \frac{dK(t)}{dt} = I - \delta K(t)$$

where K = capital, I = investment, and δ = rate of capital depreciation. The expression for the investment can be rewritten as

$$(3)\qquad I = pQ(K(t), L) - wL - D$$

where p = price of output, Q = output based upon neoclassical production function, L = labor, and w = wage rate. This equation for investment assumes that capital financing will be made from internal funds only. It will also be assumed for our analysis that prices and wages are constant. That is, the markets for the firm's product and for labor are perfectly competitive. The output function will be convex as required under the neoclassical assumptions. Furthermore,

$$(4)\qquad \begin{aligned} &0 \leq L \\ &0 \leq D \leq pQ(K(t), L) - wL \end{aligned}$$

which indicates that dividends can never exceed the net receipts, i.e., revenues minus the cost of labor.

II. Optimal Conditions

The above model is essentially the Jorgenson model for the dynamics of the firm somewhat modified. The only material modification is in the limitation on investment (3). Jorgenson assumed only that investment be nonnegative. The mathematical solution for the above problem involves the use of the Maximum Principle of Pontryagin.[1] The firm has two control variables at its disposal, dividend distribution D and the employment of labor L. These control variables are manipulated by management in order to maximize the stockholder's present value of stock. The Hamiltonian is written as[2]

$$(5)\qquad \begin{aligned} H(K, L, D, t) = {} & De^{-rt} + q(t)e^{-rt}(pQ(K(t), L) \\ & - wL - D - \delta K(t)) \end{aligned}$$

where the auxiliary variable q is interpreted as the value of a unit of investment in terms of dividends at time t. To obtain the optimal strategies for dividends and labor, the Hamiltonian is to be maximized at each instant of time with respect to dividend distribution D and labor employment L, subject to the inequalities (4). Let us first examine the characteristics of the behavior of the firm with respect to the optimal dividend distribution and holding labor constant. Since the Hamiltonian is linear in D, its maximization provides three possible optimal alternatives for dividend distribution. These are

$$(6)\qquad D = \begin{Bmatrix} 0 \\ pQ(K, L) - wL - \delta K \\ pQ(K, L) - wL \end{Bmatrix} \quad \text{if } q \begin{cases} > 1 \\ = 1 \\ < 1 \end{cases}$$

where

$$(7)\qquad \frac{dq}{dt} = -q(t)\left[p\frac{\partial Q(K, L)}{\partial K} - (\delta + r)\right] - v(t)p\frac{\partial Q(K, L)}{\partial K}$$

$$v(t) = \begin{Bmatrix} 0 \\ 1 - q \end{Bmatrix} \qquad \text{if } q = \begin{cases} \geq 1 \\ < 1 \end{cases}$$

and

$$\frac{\partial^2 Q(K, L)}{\partial K^2} \leq 0 \qquad \text{if } q = 1$$

This latter inequality is satisfied by the assumed convexity of the production function. For a given value of labor, initial value of capital and q, the growth path of the firm in time is uniquely determined by equations (2), (3), (6), and (7). These paths can be illustrated with the aid of Figures 1 and 2. Figure 1 depicts graphically two components of equations (2) and (3), that is, revenues pQ and costs $wL + \delta K$ as a function of the level of capital. Note that the depreciation of capital is part of the total costs of production. The point of maximum profits is shown to occur at K_m where the marginal revenue with respect to capital equals the slope of the cost function δ. Figure 2 is the phase plane for q and K derivable using Figure 1 and

---

[1] For the elements of this mathematical technique, refer to the text by Michael Intriligator.

[2] For convenience, the (t) will be omitted from q and K in the rest of this paper.

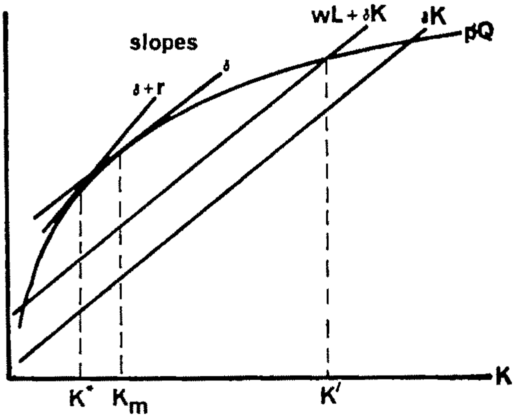

FIGURE 1. REVENUE AND COST FUNCTIONS

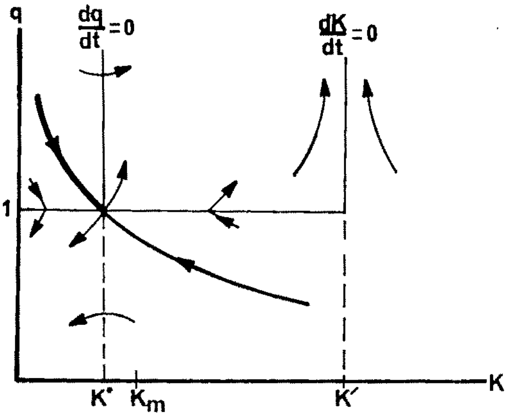

FIGURE 2. PHASE PLANE OF q AND K OPTIMAL DYNAMIC PATHS

equations (6) and (7). The trajectories of Figure 2 indicate the various optimal paths of the firm depending upon initial values of q and K. Alternatively, a specific optimal path for the firm would be determined by specifying the initial value of capital, final value of capital, and the time period.

Of particular interest is the case where the time horizon is infinite, the initial capital $K(0)$ is less than K^* shown in Figure 2, and the final level of capital is allowed to seek the optimal level. Due to this latter specification, the transversality conditions require that $q(t)e^{-rt}$ approach zero as time becomes infinite. The optimal path which satisfies these specifications and the transversality condition is shown by the bold trajectory passing through ($q=1$, K^*). The optimal path in this case would consist of two parts. (See equation (6) for $q>1$ and $q=1$.)

(i) The firm pays no dividends and allocates all net receipts for new capital.
(ii) When the level of capital K^* is reached then the only funds allocated for capital are those needed to replace depreciation. All operating profits are paid to stockholders in the form of dividends.

This trajectory has the turnpike properties found in the Optimal Growth Theory literature such as formulated by David Cass. Path (ii) could be referred to as the "dividend" turnpike and the firm could be said to be operating at its "golden stage" of production.

During the golden stage of production, dK/dt and dq/dt equal zero. That is, the level of capital is constant and the value of a unit of capital in terms of dividends is constant and equal to one. This latter condition requires

$$\frac{\partial Q(K, L)}{\partial K} = \frac{\delta + r}{p} \tag{8}$$

as derived by equation (7). This condition is a marginal productivity condition which is similar to the myopic policy derived by Arrow. The unit cost of capital in production per unit time is the rate of depreciation and the discount rate. The modification over the profit-maximizing condition consists of the discount term.

We have examined the characteristics of the firm's growth under the assumption that labor is fixed. Let us now consider the optimal path of the firm with both capital and labor as variables. Maximizing the Hamiltonian with respect to L requires that

$$\begin{gathered} \frac{\partial Q(K, L)}{\partial L} = \frac{w}{p} \\ \frac{\partial^2 Q(K, L)}{\partial L^2} \leq 0 \end{gathered} \tag{9}$$

hold true at each instant of time. That is, the level of labor employed must be such that the marginal productivity of labor equals the ratio of the unit cost of labor and the price. This condition is the same rule derived in the classical analysis of the profit maximizing firm. The second condition in (9) is a requirement of convexity of the production function relative to labor. The neoclassical assumptions of the model provide satisfaction of this condition.

Thus, the firm will put forth strategies for dividends and labor which will simultaneously satisfy conditions (i) and (9) or (ii), (8), and (9). The combination of (8) and (9) during the golden stage of production is a modified version of the marginal productivity conditions for the classical profit maximizing firm.[3] If the discount rate is zero then the golden stage conditions would be the same as the profit maximizing marginal productivity conditions. The firm in the golden stage is operating at approximately the profit-maximizing state.

An observer viewing the firm in phase (i) might interpret the firm as maximizing sales, growth, revenues, or undistributed profits. In this phase, the firm is expanding capital as rapidly as possible by withholding the distribution of dividends. Thus, the firm's growth and output as well as sales and revenues appear to be increasing as rapidly as possible. When the firm is operating in phase (ii), the observer might interpret the firm as maximizing profits or dividends. Thus, the various alternative theories of the firm noted at the beginning of this paper would all appear to be encompassed as a characteristic exhibited by wealth or stock value maximizing firms sometime during their existence.

III. Stockholder Capital Gains and Income

The results are consistent with general observation in terms of stock prices. Investors generally refer to two categories of stocks for investment, growth stocks and income stocks. Growth stocks are associated with firms which are experiencing a significant degree of expansion. These firms are characterized by little if any dividends and increasing earnings. Investors purchase growth stocks for their appreciation in value, that is, capital gains. These characteristics of growth firms are consistent with the characteristic found in the optimal firm's phase (i). That is, no dividends, increasing earnings, and appreciating value. This latter property is found by the examination of the stock value or objective function at two different time points t_0 and t_1 within phase (i). Let t^* be the time at which dividends are initially paid and phase (ii) begins. Then $t_0 < t_1 < t^*$. Since the dividend is zero in phase (i),

$$V(t_1) = \int_{t_1}^{\infty} D(t)e^{-r(t-t_1)}dt$$

$$> \int_{t_0}^{\infty} D(t)e^{-r(t-t_0)}dt = V(t_0)$$

The stock value at t_1 is greater than at time t_0 since t_1 is closer to the time at which dividends will be paid. That is, due to the discount on the dividend streams, the value at future time points during phase (i) will be greater than at current time points. This can be interpreted as value appreciation or capital gains based upon expectation of dividend payments which corresponds with observation of investor behavior and stock market prices.

Income stocks are characterized by high dividends with relatively stable earnings and relatively stable stock prices. This is consistent with phase (ii) of the optimal firm. In phase (ii), it was found that dividends and profits are constant. Since the dividends paid are constant, then for time points t_2 and t_3 where $t^* < t_2 < t_3$, $D =$ constant; we have

$$\int_{t^*}^{\infty} D(t)e^{-r(t-t^*)}dt = \int_{t_2}^{\infty} D(t)e^{-r(t-t_2)}dt$$

$$= \int_{t_3}^{\infty} D(t)e^{-r(t-t_3)}dt = \frac{D}{r}$$

---

[3] Using the classical calculus of variations, Jorgenson derived some marginal productivity conditions which differed only slightly from equations (8) and (9). However, phase (i) was not obtained by Jorgenson. It should be noted that phase (i) is not derivable with the classical machinery unless the artifice by F. A. Valentine is applied. Bounds were not placed on investment in the positive direction in the Jorgenson model.

or $V(t^*) = V(t_2) = V(t_3)$. That is, the stock value during phase (ii) at any arbitrary time point is constant. This, then, would be consistent with stable stock prices of income stocks.

IV. Summary

The above analysis has examined the optimal dynamic path of the corporate form of the firm. The owners of the corporation are the stockholders whose objective is to maximize the value of their stock. This value is defined as the present value of the discounted stream of dividends over an infinite time. The model is neoclassical. Assuming that the firm is a young firm with a limited amount of initial capital, its future behavior to be optimal would consist of two phases.

(i) *The Growth Maximization Phase* is the phase in which there is investment of all operating profit to provide new capital. No dividends are paid to the stockholders. This maximum rate of capital accumulation continues until the level of capital reaches that required for the golden stage of production. Since the firm is increasing its capital and its output as rapidly as possible, it appears to be maximizing its sales or revenues.

(ii) *The Golden Stage or the Quasi-Profit-Maximizing Phase* is the phase in which the firm behaves in a manner similar to that of the classical profit maximizing firm. That is, the firm will operate near the marginal productivity conditions. The firm will maintain the golden stage level of capital and labor employment. During this phase all operating profits are paid to the stockholders in the form of dividends. Investment is limited to replacement capital.

In effect, the firm is attempting to reach the golden stage of production as soon as possible through its growth maximization phase. Once the golden stage is reached, it is maintained.

The alternative notions to profit maximization such as revenue or sales or growth maximization, dividend maximization, undistributed profits maximization, wealth maximization, and present value maximization would not appear to be unexpected behavior of a corporation whose objective is to maximize stock value. Wealth maximization is equivalent to the objective of stock value maximization. The firm is behaving as if it were maximizing revenues, sales, or growth during phase (i). The firm is producing as much as possible by investing all operating profits in new capital which in turn will increase output.

When the firm has reached the golden stage of production then its behavior could be classified as quasi-profit maximizing or quasi-dividend maximizing. During this phase the firm is distributing all operating profits to the stockholders as dividends. The profits attained are near the level which would be dictated by the classical profit-maximizing case. The difference is due to the rate of discount which favors current dividends over future dividends. As the rate of discount approaches zero, the profits of phase (ii) will approach that of the profit-maximizing case.

The analysis has attempted to reconcile various notions regarding the behavior of the firm. Under the assumption of a neoclassical model for the dynamic firm and the objective of stock value maximization, the reconciliation would appear to be successful.

The Limits to Growth in a Neoclassical World

By MARTIN J. BECKMANN*

If some resources are exhaustible but essential to production, how should their use be allocated over time? In the presence of technical change, how much resource use is consistent with a stationary state or positive growth?

Questions like these are examined in the Club of Rome study on the limits to growth. Unfortunately, the treatment of preferences, of production technology, and of the economy appears unconventional and implausible to many economists. The following is an attempt to reformulate the allocation problem for exhaustible resources in neoclassical terms.

Preferences are described by a logarithmic utility function and future utility is discounted by a constant discount factor. Production of goods and control of bads (pollution) is described by Cobb-Douglas production functions with exogenous technical progress at constant rates. In addition to producible inputs, net inputs of exhaustible resources are needed in the production of goods. Consumption of leisure is equal to the stock of persons minus the person inputs into production, and in this way labor can be treated as any other consumption good. Under these assumptions which may be more palatable to economic theorists than those of "World Dynamics," the optimal intertemporal allocation of stocks of producible goods and of the given known stocks of exhaustible resources will be investigated.

Our objective is to maximize the present value of the stream of utility generated by consumption (flows) and by the levels of certain variables descriptive of the quality of the environment. The utility function is specified to be log-linear. Such a utility function may be interpreted in the aggregate or in per capita terms without change in the mathematics. It is chosen here because it possesses all essential features of a representative utility function and permits an explicit solution of the problem.

In a given period t let consumption of good i be c_i $i \in s_1$ and let the level of the quality variable j be $q_j j \in s_2$. The utility generated in one period is then

$$(1) \qquad u_t = \sum_{i \in s_1} a_i \log c_i + \sum_{j \in s_2} a_j \log q_j$$

where the coefficients a_i and a_j express the importance of that good or quality variable for well-being. Our objective function is then

$$\sum_{t=0}^{\infty} \rho^t u_t$$

where ρ, $0 < \rho < 1$ is the discount factor, a measure of "impatience." Consider now the technology of production. This is assumed to be Cobb-Douglas and to involve quantities X_{ik} of producible products and quantities s_{hk} of exhaustible resources. We also admit technical change at the rate μ_k. The production function is then

$$(2) \qquad y_k(t+1) = g_k e^{\mu_k t} \prod_i X_{ik}^{\gamma_{ik}}(t) \prod_h s_{hk}^{\delta_{hk}}(t)$$

In addition to producible and exhaustible resources, there may be other resources that are fixed (for example, land). Therefore, the degree of homogeneity may be less than or equal to one.

$$(3) \qquad \sum_i \gamma_{ik} + \sum_h \delta_{hk} \leqq 1$$

The level of quality variable q_j is determined by its previous level, by production activities generating pollutants (described by production inputs) and by control activities introduced to improve the level of this quality variable. The production function for quality variable j is then

$$(4) \qquad q_j(t+1) = g_j e^{\mu_j t} \prod_i X_{ij}^{\nu_{ij}}(t) \prod_h s_{hj}^{\delta_{hj}}(t) \cdot \prod_{ih} X_{ih}^{-\nu_{ihj}}(t) \prod_l q_l^{\epsilon_l}(t)$$

---

[*] Brown University and Institut für Angewandte Mathematik, Technische Hochschule München.

The exponents γ_{ij} and δ_{hj} refer as before to productive inputs into the activity that is to control or improve the quality variable, whereas the exponent ν_{ihj} refers to the generation of pollutants by other production activities.

The optimal production program is best described in terms of the "principle of optimality" of an appropriate dynamic program. Let V_n be the present value of an optimal program of production, consumption, and environmental control extended over n periods. This value depends on the state of the system as described by suitable state variables. These are: the current stocks y_i of produced commodities available for consumption or as inputs into production; the stocks z_h of exhaustible resources available for current or future input into production; the levels of the environmental quality variables q_j; and finally time t itself as an index of the state of technology.

$$(5) \quad V_n = V_n(y_1, \ldots, y_k, \ldots; z_1, \ldots, z_h, \ldots; q_1, \ldots, q_j, \ldots; \mathrm{t})$$

The principle of optimality determines the value function V_n recursively through period by period optimization. The decision to be made in every period is how much of the available quantity y_i of each producible commodity to allocate to current production of every product k, to be denoted by X_{ik}. Consumption is then

$$(6) \qquad c_i = y_i - \sum_k X_{ik}$$

Next it must be decided how much of the available stocks z_h of exhaustible resources h should be used in the production of goods k, s_{hk}. Similarly amounts X_{ij}, s_{kj} must be allocated to the control activities for environmental quality variables q_j. In order to determine the value function, let $V_0=0$. Optimization in a single period requires then that all stocks of products k be consumed.

$$(7) \quad V_i = \sum_i a_i \log y_i + \sum_j a_j \log q_j$$

Now let V_{n-1} be known. The state variables in V_{n-1} depend on the decision variables x_{ik}, s_{hk} in the current period through the production functions (2) and (4). Moreover,

$$(8) \qquad z_h(\mathrm{t}+1) = z_h(\mathrm{t}) - \sum_i s_{hi}$$

The general format of the principle of optimality is

$$(9) \quad V_n(y, z, q, \mathrm{t}) = \max_{x_{ih}, s_{ih}} u\left(y_i - \sum_h x_{ihj} \ldots\right) + \rho V_{n-1}\left[y_k(x_{ih}, s_{ih}), z_h - \sum_i s_{hi}, q_j(\ldots x_{ih} \ldots x_{ij}, s_{hj}, q_t, \mathrm{t})\right]$$

With log-linear utility and production functions it can be shown that the value function is also log-linear

$$(10) \quad V_n = b_{n0} + \beta\mathrm{t} + \sum_k b_{nk} \log y_k + \sum_j b_{nj} \log q_j + \sum_h b_{nh} \log z_h$$

and is linear with respect to time. This is demonstrated for a three-variable model below. In this proof it is also shown that the allocations x_{ik} and s_{hk} are strictly proportional to the available stocks:

$$(11) \qquad x_{ik} = \frac{\alpha_{ik}}{1 + \sum_k \alpha_{ik}} y_i$$

$$(12) \qquad s_{hk} = \frac{\lambda_{hk}}{1 + \sum_k \lambda_{hk}} z_h$$

Let now the planning horizon n be infinite. For the aggregate use of exhaustible resources in every period one obtains a remarkably simple rule: In every period the constant fraction $1-\rho$ of the remaining stock of every exhaustible resource should be used up.

$$(13) \qquad \sum_k s_{hk} = (1-\rho) z_h$$

This fraction is larger the smaller the discount factor ρ for future utility. It is approximately equal to the associated interest rate expressed as a fraction.

$$1-\rho = 1-\frac{1}{1+i} \cong 1-(1-i) = i$$

What are the economic consequences of these decision rules? We will discuss these in terms of a simplified model involving only one producible commodity which is both input and consumption good y, an exhaustible resource z, and one environmental quality variable q. To begin with assume that environmental quality is no problem so that q is also dropped. The utility function is

$$u = a\,log\,(y-x) \tag{14}$$

and the production function

$$y = ge^{\mu t}x^{\gamma}s^{\delta} \qquad \gamma+\delta \leq 1 \tag{15}$$

The dynamic program assumes the form

$$\begin{aligned}b_0+\beta t+b_1\,log\,y+b_2\,log\,z = \\ \operatorname*{Max}_{x,s}\{a\,log\,(y-x)+\rho[b_0+\beta t \\ +b_1\,log\,(ge^{\mu t}X^{\gamma}s^{\delta}) \\ +b_2\,log\,(z-s)]\}\end{aligned} \tag{16}$$

Maximization with respect to x and s requires

$$\frac{-a}{y-x}+\rho b_1\frac{\gamma}{x} = 0 \tag{17}$$

$$\frac{b_1\delta}{s}-\frac{b_2}{z-s} = 0 \tag{18}$$

From (17)

$$x = \frac{\rho b_1\gamma}{a+\rho b_1\gamma}\,y \tag{19}$$

and from (18)

$$s = \frac{b_1\delta}{b_2+b_1\delta}\,z \tag{20}$$

Substitution in (16) yields

$$b_1 = \frac{a}{1-\rho\gamma} \tag{21}$$

and

$$b_2 = \frac{\rho}{1-\rho}\,b_1\delta \tag{22}$$

Therefore,

$$\frac{s}{z} = \frac{b_1\delta}{b_2+b_1\delta} = \frac{1}{1+\dfrac{\rho}{1-\rho}} = 1-\rho \tag{23}$$

$$\frac{x}{y} = \frac{\rho b_1\gamma}{a+\rho b_1\gamma} = \frac{\dfrac{\rho a\gamma}{1-\rho\gamma}}{a+\dfrac{\rho a\gamma}{1-\rho\gamma}} = \rho\gamma \tag{24}$$

Thus

$$z(t) = z(0)\rho^{t} \tag{25}$$

$$s(t) = z(0)(1-\rho)\rho^{t} \tag{26}$$

The production function is then

$$y(t+1) = ge^{\mu t}(\rho\gamma)^{\gamma}y(t)^{\gamma}\rho^{t\delta}(1-\rho)^{\delta}z(0)^{\delta} \tag{27}$$

In logarithmic terms

$$\begin{aligned}log\,y(t+1) = log\,g+\mu t+\gamma\,log\,\rho\gamma \\ +t\delta\,log\,\rho+\delta\,log\,(1-\rho) \\ +\delta\,log\,z(0)+\gamma\,log\,y(t)\end{aligned} \tag{28}$$

or $\eta(t+1) = m+nt+\gamma\eta(t)$

where $\eta = log\,y$. This is solved by

$$\eta(t) = c(t)+d+w(t) \tag{29}$$

where

$$c = \frac{n}{1-\gamma} \tag{30}$$

$$d = \frac{m-\dfrac{n}{1-\gamma}}{1-\gamma} \tag{31}$$

and $w(t)$ is the solution of the homogeneous equation $\eta(t+1) = \gamma\eta(t)$.

$$\text{The system is}\left\{\begin{matrix}\text{growing}\\ \text{stationary}\\ \text{declining}\end{matrix}\right\}\text{according as } n\left\{\begin{matrix}>\\ =\\ <\end{matrix}\right\}0.$$

But

$$n = \mu+\delta\,log\,\rho \tag{32}$$

To avoid decline, technical change in μ must be rapid enough to offset $\delta|log\ \rho|$ which is larger the smaller is ρ. To put it differently, the largest rate of resource use consistent with a stationary state is

$$1 - \beta = 1 - e^{-\mu/\delta} \tag{33}$$

It is larger the larger the rate of technical change μ and the smaller the output elasticity δ of the exhaustible resource. Thus with $\mu = 0.03$ and $\delta = 0.1$ (say) the permissible rate of resource use per period is 26 percent.

Let now one environmental quality variable q be included. The utility function is then

$$u = a_1\, log\,(y - X_1 - X_2) + a_2\, log\, q \tag{34}$$

and the production functions are

$$y = g_1 e^{\mu_1 t} X_1^{\gamma_1} s_1^{\delta_1} \qquad \gamma_1 + \delta_1 \leq 1 \tag{35}$$

$$q' = g_2 e^{\mu_2 t} X_1^{-\nu} X_2^{\gamma_2} s_2^{\delta_2} q^{\epsilon} \tag{36}$$

where q' denotes the quality level of the next period. The principle of optimality of the dynamic program is

$$\begin{aligned} &b_0 + \beta t + b_1\, log\, y + b_2\, log\, q + b_3\, log\, z \\ &= \operatorname*{Max}_{x_1, x_2, s_1, s_2} \{a_1\, log\,(y - X_1 - X_2) + a_2\, log\, q \\ &\quad + \rho[b_0 + \beta t + b_1\, log\,(g_1 e^{\mu_1 t} X_1^{\gamma_1} s_1^{\delta_1}) \\ &\quad + b_2\, log\,(g_2 e^{\mu_2 t} X_1^{-\nu} X_2^{\gamma_2} s_2^{\delta_2} q^{\epsilon}) \\ &\quad + b_3\, log\,(z - s_1 - s_2)]\} \end{aligned} \tag{37}$$

Maximization with respect to X_1, X_2, yields

$$\frac{-a_1}{y - X_1 - X_2} + \frac{\rho b_1 \gamma_1}{X_1} - \frac{\rho b_2 \nu}{X_1} = 0 \tag{38}$$

$$\frac{-a_1}{y - X_1 - X_2} + \frac{\rho b_2 \gamma_2}{X_2} = 0 \tag{39}$$

from which

$$X_1 = \frac{b_1\gamma_1 - b_2\nu}{\dfrac{a_1}{\rho} + b_1\gamma_1 + b_2\gamma_2 - b_2\nu}\, y \tag{40}$$

$$X_2 = \frac{b_2\gamma_2}{\dfrac{a_1}{\rho} + b_1\gamma_1 + b_2\gamma_2 - b_2\nu}\, y \tag{41}$$

Maximizing with respect to s_1 and s_2 yields

$$\frac{b_1\delta_1}{s_1} - \frac{b_3}{z - s_1 - s_2} = 0$$

$$\frac{b_2\delta_2}{s_2} - \frac{b_3}{z - s_1 - s_2} = 0$$

$$\frac{s_2}{s_1} = \frac{b_2\delta_2}{b_1\delta_1} \tag{42}$$

from which (and equation (13))

$$s_1 = \frac{1 - \rho}{1 + b_2\delta_2/b_1\delta_1}\, z \tag{43}$$

$$s_2 = \frac{1 - \rho}{1 + b_1\delta_1/b_2\delta_2}\, z \tag{44}$$

Substituting in the production function and writing $\eta = log\ y$ as before

$$\begin{aligned} \eta(t + 1) &= log\, g_1 + \mu_1 t \\ &\quad + \gamma_1\, log\, \frac{b_1\gamma_1 - \nu b_2}{\dfrac{a_1}{\rho} + b_1\gamma_1 + b_2\gamma_2 - b_2\nu} \\ &\quad + \gamma_1\eta(t) + \delta_1\, log\, \frac{1}{1 + \dfrac{b_2\delta_2}{b_1\delta_1}} \\ &\quad + \delta_1 t\, log\, \rho \end{aligned} \tag{45}$$

This is again of the form

$$\eta(t + 1) = m + nt + \gamma_1\eta(t)$$

and is solved by

$$\eta(t) = ct + d + \omega(t) \tag{46}$$

where $\omega(t)$ is the solution of the homogeneous equation

$$\eta(t + 1) = \gamma_1\eta(t) \tag{47}$$

which may be disregarded in the long run (as before) since

$$\omega(t) = \gamma_1^{t}\omega(0) \rightarrow 0 \tag{48}$$

since $0 < \gamma_1 < 1$. Now the coefficients in (46) are

$$c = \frac{n}{1-\gamma} \tag{49}$$

$$d = \frac{m - \dfrac{n}{1-\gamma}}{1-\gamma} \tag{50}$$

Again output is $\left\{\begin{matrix}\text{increasing}\\ \text{stationary}\\ \text{declining}\end{matrix}\right\}$ according as

$$n = \mu_1 + \delta_1 \mathit{log}\, \rho \left\{\begin{matrix} > \\ = \\ < \end{matrix}\right\} 0.$$

As an additional requirement for feasibility of long-run production we have that the coefficient of X_1 be positive.

$$b_1\gamma_1 - b_2\nu > 0 \tag{51}$$

which imposes an upper bound on the pollution elasticity ν. Consider next the quality of the environment

$$\mathit{log}\, q(\mathrm{t}) = \kappa(\mathrm{t}) \tag{52}$$

$$\begin{aligned} \kappa(\mathrm{t}+1) &= \mathit{log}\, g_2 + \mu_2\mathrm{t} - \nu\, \mathit{log}\, X_1 \\ &\quad + \gamma_2\, \mathit{log}\, X_2 + \delta_2\, \mathit{log}\, s_2 + \epsilon\kappa(\mathrm{t}) \\ &= \text{constant} + \mu_2\mathrm{t} + \delta_2\mathrm{t}\, \mathit{log}\, \rho \\ &\quad + (\gamma_2 - \nu)[\mu_1 + \delta_1\, \mathit{log}\, \rho]\mathrm{t} + \epsilon\kappa(\mathrm{t}) \end{aligned} \tag{53}$$

by the same argument as for output $\eta(\mathrm{t})$. This is increasing or stationary, whenever

$$\begin{aligned} &\mu_2 + \delta_2\, \mathit{log}\, \rho \\ &\qquad + (\gamma_2 - \nu)[\mu_1 + \delta_1\, \mathit{log}\, \rho] \geqq 0 \end{aligned} \tag{54}$$

or

$$\rho \leqq \exp\,[(\mu_2 + (\gamma_2 - \nu))/(\delta_2 + (\gamma_2 - \nu)\delta_1)] \tag{55}$$

A further possibility is that output increases and the quality of the environment declines (or vice versa) while the utility level increases or is stationary. Now utility is

$$u = \text{constant} + a_1\eta(\mathrm{t}) + a_2\kappa(\mathrm{t}) \tag{56}$$

and this is a linear function of time.

$$\begin{aligned} u(\mathrm{t}) = \text{constant} &+ a_1[\mu_1 + \delta_1\, \mathit{log}\, \rho]\mathrm{t} \\ &+ a_2[\mu_2 + \gamma_2\mu_1 - \nu\mu_1 \\ &\qquad + (\delta_2 + (\gamma_2 - \nu)\delta_1)\, \mathit{log}\, \rho]\mathrm{t} \end{aligned} \tag{57}$$

The condition for utility not to decline is, therefore,

$$\begin{aligned} &a_1\mu_1 + a_2\mu_2 + a_2(\gamma_2 - \nu)\mu_1 \\ &\quad + [a_1\delta_1 + a_2\delta_2 + a_2\gamma_2 - \nu\delta_1]\, \mathit{log}\, \rho \geqq 0 \end{aligned} \tag{58}$$

from which

$$\begin{aligned} &1 - \rho \leq 1 \\ &\quad - \exp\left\{-\frac{a_1\mu_1 + a_2\mu_2 + a_2(\gamma_2 - \nu)\mu_1}{a_1\delta_1 + a_2\delta_2 + a_2(\gamma_2 - \nu)\delta_1}\right\} \end{aligned} \tag{59}$$

In any case positive technical progress is required in order that resource exhaustion should not lead to an eventual inevitable decline of the utility level. The rate of technical change properly weighed with the coefficients of the utility and the elasticities of the production function impose an upper bound on the permissible rates of exhaustion. As an illustration suppose that $a_1 = a_2$, $\mu_1 = \mu_2 = 0.03$. $\delta_1 = \delta_2 = 0.2$, $\gamma_1 = \gamma_2 = 0.8$, $\nu = 0.1$. Then

$$1 - \hat{\rho} \leq 1 - e^{-0.15}$$

$$1 - \hat{\rho} \cong 14 \text{ percent} \tag{60}$$

Capital Gains and the Aggregate Consumption Function: Comment

By MICHAEL B. MCELROY AND J. C. POINDEXTER*

A direct causal relationship between capital gains and consumption expenditures was hypothesized by J. M. Keynes in the *General Theory* (pp. 92–94). Only recently, however, have empirical studies of the consumption function attempted to verify this relationship. Making use of his own empirical estimates of accrued capital gains and losses, Kul Bhatia, in a recent article in this *Review*, claims to have done the following:

> We incorporate capital gains into the permanent income framework and test several hypotheses about the effect of capital gains on aggregate consumption. . . . To anticipate the conclusions of the paper, when an appropriate distributed lag function is specified, both accrued and realized capital gains turn out to be significant variables in the aggregate consumption function. [p. 866]

However, Bhatia's statistical results and therefore the ". . . important implications for taxation and other areas of economic analysis and policy" (p. 876) that he draws are called into question when some tenuous and highly restrictive aspects of his specification of the consumption function are amended. In this note we argue that Bhatia's model: (a) includes the same variable, capital gains, twice—once as a separate argument and again in the net worth term; (b) unjustifiably constrains the coefficients on expected gains and initial wealth to be equal; (c) assumes money illusion by failing to eliminate purely inflationary increments from the capital gains series; and (d) incorrectly employs only nominal measures of the variables in the empirical estimation.

In his wealth approach formulation of the consumption function,[1] Bhatia estimates permanent income as the sum of expected disposable labor income (Y_t^w) and expected income from wealth (βW_t^*) where W_t^* is an "expected wealth" variable as discussed below and β is the "normal return" on wealth. He then fits the following function:

$$C_t = kY_t^w + k\beta W_t^*$$

or, letting $W_t^* = W_{t-1} + \omega(L)G_t$,

$$C_t = kY_t^w + k\beta W_{t-1} + k\beta\omega(L)G_t \tag{1}$$

where C_t is consumption in period t, W_{t-1} is wealth at the end of the previous period, $\omega(L)$ is a lag operator, and G_t is the accrued capital gain (or loss) in period t.[2] According to Bhatia, "The term W_t^* . . . is a subjective value concept which differs from the actual market value of wealth inasmuch as it includes *expected* gains $[G_t^e]$ whereas only *actual* gains would be included in W_t. . . . If our specification is valid, the gains' coefficient in [(1)] should be positive and significant" (p. 868).

---

* North Carolina State University. We are grateful to Bhatia for making some of his unpublished data available to us and to T. Dudley Wallace for helpful discussions.

[1] Bhatia distinguishes between an "income" and a "wealth" approach to incorporating capital gains as an independent variable in the aggregate consumption function. We restrict our comments to the latter formulation since his empirical tests using the income approach fail to support his hypothesis that capital gains are a significant determinant of consumer spending. Bhatia contends that the regression results obtained in the wealth approach confirm the hypothesis that both accrued and realized capital gains affect consumption (via wealth), but he gives no theoretical rationale for preferring this specification over the income approach. Even if we did not have reason to doubt the validity of his specification and testing of the wealth approach, we would be skeptical of his assertion, based primarily on a comparison of the Durbin-Watson statistics, that these results appear "much sharper" (p. 875). The Durbin-Watson statistic may not be a particularly appropriate criterion for choosing between these two specifications. In regressions involving a lagged dependent variable (past consumption is a component of the lagged income term), this statistic is biased toward indicating no serial correlation.

[2] We are primarily concerned with the accrued gains-consumption relationship since, as Bhatia notes, two-way causation is likely to be a problem when testing for the role of realized capital gains. There is evidence that individuals may realize their gains *after* the consumption decision has been made. Furthermore, the realization process is simply an asset transformation and while its influence on consumption behavior is certainly not without interest, it is far less basic than the accrued

However, the specification is not valid. The market value of wealth at the end of the preceding period (W_{t-1}) *already embodies* expectations of future income from asset holdings. Even if individuals should extrapolate past capital gains experience in the manner assumed by Bhatia (a distributed lag expectation model), all of their experience through the end of the preceding period ($t-1$) would be reflected in the expectation in period $t-1$ of future gains and, unless asset markets are seriously flawed (an argument which Bhatia does not rely on), those expectations would be fully capitalized and reflected in W_{t-1}. The only additional information on expected future capital gains that would be provided by Bhatia's distributed lag function on capital gains would come from the current period's gain G_t.

This flaw in Bhatia's wealth approach may be seen more clearly by spelling out the components of the wealth term. While W_{t-1} consists of more than just accumulated capital gains (all net capital formation is included), it must include $(G_{t-1}+G_{t-2}+\ldots+G_{t-n}+\ldots)$. Bhatia's expected capital gains function in equation (1) takes the form $(\omega_0 G_t+\omega_1 G_{t-1}+\omega_2 G_{t-2}+\ldots+\omega_n G_{t-n}+\ldots)$. Equation (1) clearly fails to perform the test Bhatia intends for the independent, separable effect of capital gains on consumption. The only term appearing in the expected capital gains variable that does not also appear in the expression for W_{t-1} is $\omega_0 G_t$, weighted *current* capital gains.

Deleting the repetitive lagged terms in his specification yields:

$$C_t = k_0 Y_t^w + k_0\beta W_{t-1} + k_1 G_t \tag{2}$$

which, fitted with Bhatia's data, gives[3]

$$\underset{}{C_t =} \underset{(39.20)}{.780Y_t^w} + \underset{(4.19)}{.052W_{t-1}} + \underset{(0.56)}{.008G_t}$$

Bhatia is right to argue that this equation showing a statistically insignificant role for capital gains does not test for the independent effect of previous capital gains on consumption. However, neither does his equation (1).

A second basic shortcoming in Bhatia's analysis is that he constrains the coefficient ($k\beta$ in equation (1)) on expected capital gains (G_t^e) to be equal to the coefficient on last period's measured wealth. It appears that this restriction accounts for the statistical significance of his capital gains term. This is shown in Table 1, which summarizes the results we obtained using Bhatia's data and lag weights in regressions on equation (1) both with and without the equality constraint. The unconstrained estimates (3) and (4) yield about the same coefficients on the income and wealth terms as the constrained form (1) and (2). But relaxing the equality constraint results in a statistically insignificant coefficient on accrued gains.[4] Hence, Bhatia's results depend upon a critical behavioral hypothesis—that individuals treat all increments to their net worth identically in their consumption decision. This hypothesis is not supported by his data.

The lack of richness of the data does not

---

gains-consumption relationship. In other words, the coefficient on realized gains represents the effect of a particular change in the *composition* of wealth on consumption, whereas the coefficient on accrued gains represents the effect of a change in the *level* of wealth on consumption.

[3] Expected labor income (Y_t^w) was generated using a second-degree Almon lag operator to approximate a fourth-degree polynominal lag. These results are consistent with earlier findings such as those of John Arena. The t-statistics are in parentheses below the coefficients. The R^2 for this regression is .999, the *D.W.* is 1.74, and the *SEE* is 2.32. The sums of squared errors were 44.85 and 43.0, respectively, for equations (1) and (2) in our regressions with Bhatia's data, indicating that no explanatory power is lost by deleting the repetitive terms.

[4] Though we have focused on the accrued gains-consumption relationship, it should be noted that dropping the equality constraint also causes the coefficient on realized gains to become statistically insignificant.

TABLE 1—ESTIMATES OF THE COEFFICIENTS OF BHATIA'S WEALTH APPROACH WITH AND WITHOUT THE EQUALITY CONSTRAINTS
(for accrued capital gains)[a]

	Constant	Y_t^w	W_t^*	W_{t-1}	G_t^e	*SEE*	R^2	*DW*
1)	4.792	.702	.062			2.08	.999	1.96
	(0.54)	(5.22)	(3.27)					
2)		.790	.052			2.02	.999	1.66
		(19.78)	(7.28)					
3)	4.860	.699		.062	.077	2.19	.999	1.93
	(0.52)	(4.89)		(3.12)	(0.90)			
4)		.793		.051	.037	2.11	.999	1.70
		(17.89)		(6.89)	(0.54)			

[a] Regressions 1) and 2) impose the equality constraint on the coefficients of expected capital gains. Regressions 3) and 4) drop this constraint. All variables are in billions of dollars and *t*-statistics are given in parentheses below the coefficients.

permit us to reject the hypothesis that the coefficients on the lagged wealth and expected capital gains terms are equal. However, neither is it capable of refuting the hypothesis that accrued capital gains have *no place* in the consumption function.

Another point that should be noted in evaluating Bhatia's results is that he measures capital gains accruing in period t as the change in net worth ($W_t - W_{t-1}$) not attributable to measured net capital formation (I_t), i.e.,

$$G_t \equiv W_t - W_{t-1} - I_t$$

When changes in the price level occur, the variables on the right-hand side of this identity will be measured in different units, introducing an illusory increment into his measure of accrued gains. There seems to be no a priori rationale for building this money illusion into the consumption function. A more useful measure of accrued capital gains, net of the inflationary increment, would be:

$$G_t' \equiv W_t - \left(\frac{P_t}{P_{t-1}}\right) W_{t-1} - \left(\frac{P_t}{\bar{P}_t}\right) I_t$$

where P_t is an end of period t implicit price deflator and $\bar{P}_t$ is an "average" implicit price deflator for period t.[5] This is still in current dollars but eliminates Bhatia's mismeasurement by converting all the terms on the right-hand side into the same units. Even with an otherwise correctly specified consumption model, a significant coefficient on his G_t term could result from the correlation between this inflationary increment and the price component of the *nominal* consumption measure he employs.[6]

It should also be stressed that all of Bhatia's variables are measured in current rather than constant dollars. His failure to deflate is puzzling indeed since, as is well known, this results in a further element of spurious correlation in the estimated coefficients.

We agree with Bhatia that the role of capital gains in consumption has important policy implications. However, we do not believe that his analysis has added to our knowledge in this area. He argues that earlier studies of the role of capital gains in the consumption function failed to find any significant influence because ". . . capital gains have not been studied in an appropriate theoretical model" and because no ". . . direct estimates of gains have been used in empirical estimation" (p. 866). We have argued that he has not provided an "appropriate" model since his expected capital gains term is not independent of lagged wealth. Moreover, he has confused assumption with empirical finding by building an empirically unverified constraint into the capital gains coefficient. Thus, his policy conclusions for the economic effects of capital gains taxation are based on an *assumed*, not a statistically verified, behavioral relationship. Finally, we contend that Bhatia's estimates of accrued capital gains are inappropriate for the tests he performs and that his use of nominal measures throughout cannot be justified. Empirical verification of the intuitively reasonable hypothesis that real accrued capital gains and losses do affect the consumption decision remains elusive.

---

[5] This adjustment makes a significant difference in the magnitude, alters the year-to-year variation, and occasionally even changes the sign of estimated accrued capital gains. For example, McElroy, using a slightly broader base for estimating capital gains, found that "gross" money gains G from 1946 through 1968 totalled \$1173 billion, whereas "net" money gains G' were \$598 billion.

[6] The simple correlation between P and ΔP is $-.30$.

Capital Gains and the Aggregate Consumption Function: Reply

By KUL B. BHATIA*

Michael McElroy and J. C. Poindexter (M-P hereafter) seek to demolish the theoretical structure and the main findings of my paper in their comment. However, their criticisms are not well founded and are highly conjectural in nature. Their major criticism about the specification of the "wealth approach" is invalid, they do not exactly duplicate the statistical tests used in my paper, and they do not show how the data adjustments proposed by them will affect the final results.

I. Equations in the Wealth Approach

The consumption function in the wealth approach in my paper (equation (6)) is $C_t = kY_t^w + k\beta W_t^*$ where k is the marginal propensity to consume permanent income, "β is the 'normal return' on wealth, and W_t^* is the expected wealth relevant for making consumption decisions in period t . . ."; W_t^* is defined as "the sum of actual wealth at the end of the previous period (W_{t-1}), and a lagged function of accrued capital gains [$W(L)G_t$]" (p. 868). Substitution for W_t^* in (6) yields

$$C_t = kY_t^w + k\beta W_{t-1} + k\beta W(L)G_t$$

which is equation (8) in the paper. M-P contend that there are two basic flaws in this analysis: first, it ". . . includes the same variable, capital gains, twice—once as a separate argument and again in the net worth term," and second, it ". . . unjustifiably constrains the coefficients on expected gains and initial wealth to be equal" (p. 700). . . . "It appears that this restriction accounts for the statistical significance of his capital gains term" (p. 701). Consequently, they delete the "repetitive lagged terms" and present unconstrained estimates in their Table 1. As the following discussion will show, both these points relate to the expected wealth term W_t^* in the consumption function.

A. *The Specification of Expected Wealth* (W_t^*)

The derivation of W_t^* in my paper can be elaborated on as follows:

$$(1) \qquad W_t \equiv W_{t-1} + A_t + G_t$$

$$(2) \qquad W_t^* = W_{t-1} + G_t^e$$

$$(3) \qquad G_t^e = W(L)G_t$$

where W_t and W_t^* are as defined above; A_t and G_t, respectively, are net acquisitions and accrued capital gains during t; and the expected accrued gains during t are denoted by G_t^e which is derived from a distributed lag function of current and past accrued gains. For the empirical results derived in the paper, $W(L)G_t$ was defined by a geometric lag function $(1-\lambda)\ \sum_{i=0}^{t} \lambda^i G_{t-i}$. Using this specification we get:

$$(4) \qquad W_t^* = W_{t-1} + \sum_{i=0}^{t} w_i G_{t-i}$$

where $w_0 = (1-\lambda)$, $w_1 = \lambda(1-\lambda)$,
$w_2 = \lambda^2(1-\lambda)$, etc.

M-P object to equation (4) because W_{t-1} already includes G_{t-1}, G_{t-2}, etc., and these are also present in the expected gains term, G_t^e. Deleting the repetitive lagged terms, they write the consumption function (their equation (2)) as

$$C_t = k_0 Y_t^w + k_0\beta W_{t-1} + k_1 G_t$$

which implies

$$(5) \qquad W_t^* = W_{t-1} + w_0 G_t$$

But why should the repetitive lagged terms be deleted? If we lag equation (1) by one period, and the terms on the right-hand side successively, we derive:

---

* University of Western Ontario. Thanks are due to my colleagues C. Scott Clark and E. J. D. Ketchum for helpful discussions.

$$(1') \quad W_{t-1} = W_0 + \sum_{i=1}^{t} G_{t-i} + \sum_{i=1}^{t} A_{t-i}$$

where W_0 is initial wealth. In other words, the market value of wealth at the end of year $t-1$ is the sum of initial wealth (W_0), all gains which have accrued until then ($\sum G_{t-i}$), and net acquisitions ($\sum A_{t-i}$). Substituting (1′) into (4) and regrouping terms gives

$$(6) \quad W_t^* = W_0 + \sum_{i=1}^{t} A_{t-i} + w_0 G_t + \sum_{i=1}^{t} (1 + w_i) G_{t-i}$$

To derive M-P's equation (2), (6) has to be supplanted by (5). This implies that $W_{t-1} = W_0 + \sum_{i=1}^{t} A_{t-1} + \sum_{i=1}^{t} (1+w_i) G_{t-i}$, which violates (1) and (1′) unless $w_i (i=1, 2, \ldots t) = 0$. Alternatively, if $w_i (i=1, 2, \ldots t)$ are indeed zero, equation (3) is contradicted. Either contradiction has rather serious implications. If equation (3) holds, W_{t-1} depends directly on w_i which are the weights that minimize the residual sum of squares and yield the maximum likelihood estimates of the consumption function (see fn. 17 in the original paper). On the other hand, if $w_i (i=1, 2, \ldots)$ are zero, it implies that expectations about future gains are based on accrued gains for the current period only. Both (1) and (1′) are well established and widely used accounting definitions of market value of wealth, and the expectations mechanism in equation (3) is an important element of the literature on the permanent income hypothesis and distributed lags. Deleting the repetitive lagged terms involves a contradiction which M-P do not seem to recognize. Their justification for this deletion is vague and unconvincing. They do not appear to reject the expectations mechanism in their comment, but on page 701 they state, "The market value of wealth at the end of the preceding period (W_{t-1}) *already embodies* expectations of future income from asset holdings." Might we assume, therefore, that M-P are offering a new definition of market value of wealth which includes regression parameters?

Another objection raised by M-P is implied by their remark that if lagged gains are included in both W_{t-1} and G_t^e, one cannot perform a test "for the independent, separable effect of capital gains on consumption" (p. 701). This is a statistical argument, not a theoretical one, and its force depends on whether the constrained estimation used in my paper is justified or not. Before dealing with this issue, however, it should be emphasized that, as the discussion here clearly shows, the wealth equations in my paper are correctly specified and consistent with the theoretical framework set out there. M-P's equation (2) and equations (3) and (4) in their Table 1 do not follow from the model presented in my paper.

B. *Constrained vs. Unconstrained Estimation*

For deriving the empirical results in my paper the coefficients of W_{t-1} and G_t^e are constrained to be equal because W_t^* is defined by (2). The constraint thus follows directly from the theoretical specification of the consumption function and implies that expected income from wealth (βW_t^*), irrespective of the components of W_t^*, is the relevant variable (besides other permanent income) for consumption decisions. Even as a practical matter, it is reasonable to assume that changes in market value of net worth, whether caused by variations in asset prices or net acquisitions, will have the same effect on consumption. A case could perhaps be made that people treat, say, corporate stock holdings differently from real estate holdings, but to treat net acquisitions and *expected* capital gains on the same asset differently does not seem very plausible.

In this context, it is easy to speculate but difficult to test whether the constraint accounts for the statistical significance of the capital gains term. The test conducted by M-P is incorrect because it is inconsistent with the theoretical model in my paper. To perform the test correctly, let us define W_t^i as the sum of initial wealth and all past net acquisitions.

$$W_t' = W_0 + \sum A_{t-i} \tag{7}$$

$$W_t = W_t' + \sum_{i=0}^{t} G_{t-i} \tag{8}$$

W_t' thus is different from W_t because it does not include any capital gains. If wealth and expected gains have different coefficients, the consumption function can be rewritten as

$$C_t = k_0 Y_t^{\omega} + k_1 W_{t-1} + k_2 G_t^{e} \tag{9}$$

Substituting from (8) for W_{t-1} and using the specification $G_t^e = \sum w_i G_{t-i}$ yields

$$C_t = k_0 Y_t^{\omega} + k_1 W_{t-1}' + k_1 \sum_{i=1}^{t} G_{t-i} + k_2 \sum w_i G_{t-i}$$

or

$$C_t = k_0 Y_t^{\omega} + k_1 W_{t-1}' + k_2 w_0 G_t + \sum_{i=1}^{t} (k_1 + w_i k_2) G_{t-i} \tag{10}$$

The correct unconstrained form of the consumption function thus is provided by (10). It calls for complicated, non-linear estimation which definitely lies outside the scope of this brief reply. In their Table 1, M-P report two regression estimates of equation (9), and not of equation (10). That clearly is not a test of the constraint specified in the theoretical model of my paper.[1]

II. The Measurement of Accrued Gains

M-P also criticize my use of nominal rather than real magnitudes, and the measure of capital gains adopted in my paper. As a general proposition, I agree that wherever possible aggregate consumption functions should be estimated not only in real but also in per capita terms. My choice of nominal variables, therefore, is based mainly on empirical considerations.

The task of computing even ***nominal*** gains is beset with enormous data difficulties caused by conflicting series on market value, missing data, incomplete information in several areas, and highly deficient documentation of published series. Corporate stock accounted for more than 60 percent of all accrued gains between 1948 and 1964, the time period covered by my study. As discussed at length in my 1973 paper, several adjustments were necessary to derive consistent estimates of nominal gains accruing on corporate stock. Estimating real gains, as M-P recognize, is not a matter of simply deflating nominal gains by a price index. It requires deflation of the asset holdings at the beginning of a year, at the end of the year, and also of net acquisitions during the year. Now, ignoring for the moment the problem of unsatisfactory deflators, there are no adequate data on net acquisitions of corporate stock.[2] Therefore, although some indirect procedures are possible, they will further complicate, and perhaps also introduce additional errors, in estimating ***real*** capital gains. The use of nominal variables throughout is the obvious next-best solution.

Another difficulty caused by using real gains is that with changes in price level, gains or losses will accrue on all assets whose face values are fixed in nominal terms. Thus, in an inflationary situation, losses will accrue on people's cash balances, demand deposits, etc., and gains will accrue on the net borrowing of households from other sectors of the economy. Estimating gains and losses on these additional items will create further problems because of inadequacies in the available data.

Although M-P's representation of my method of estimating gains is only partly accurate,[3] their point, also stated in my paper (p. 870, fn. 9), is correct that no adjustment for changes in price level is made in deriving the

---

[1] A statistical point about the results in Table 1 should also be noted: M-P use the weights for Y_t^{ω} and G_t^e derived in estimating 1) and 2), also in equations 3) and 4). (This is not stated in the comment but has been confirmed by McElroy in a letter to the author.) These weights were estimated in the regression results reported in my paper. Since they were optimally chosen for equations 1) and 2), it is doubtful whether they minimize the residual sum of squares of equations 3) and 4) in Table 1 (see fn. 17 of my paper for details of the search procedure by which the optimal weights were selected). Even on its own ground, therefore, M-P's test is statistically unsound.

[2] For a critical discussion of the data on net acquisitions of corporate stock, see the author (1973), pp. 56–58, and the references cited there.

[3] For my paper, accrued gains on farm assets and

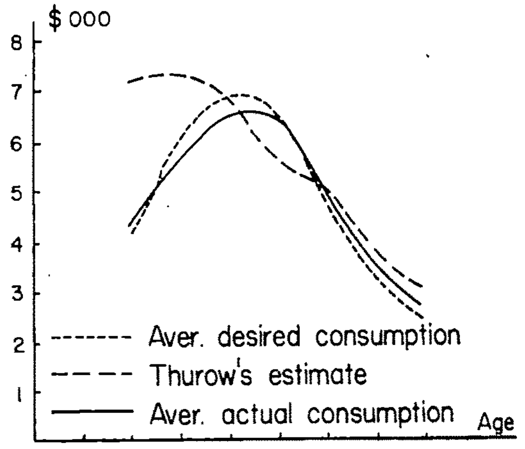

FIGURE 6

Taking the percentile profiles in Figure 3 to approximate income profiles at different levels of wealth, we associate with each a homothetic transform of the average income profile (the coefficient, in each case, being such that the transform coincides with the associated profile at age 50), and the deviations at each age between profiles and transforms are used to obtain the following rough estimates of $r(A)$.[19]

Age:	20	30	40	50	60	70	80
$r(A)$:	−1263	−1595	−963	0	1910	2808	3211

Introducing these estimates together with $p=0.80$ and Census measures of $F(A)$ in relation (29′), we obtain the corrected estimates of $g(A)$ shown as a thick dotted line in Figure 6. *They do reveal an average pattern of desired consumption above actual in the age range 25 to 45, with maximum discrepancy at age 35, but the gap is small in relation to that calculated by Thurow, and it occurs over a later period of the life cycle.*[20] It would appear, in particular, that the very young would continue to opt for the less expensive pleasures of life were the capital market open more widely to them.

E

One disturbing feature of the desired-consumption profile estimated in the previous section is that it exceeds actual consumption over a range (age 25–45) in which income is itself higher than consumption: If the average-income household wishes to consume more in that range, why does it not do so by spending more of its income? The main answer, of course, is that the definition of consumption used so far excludes personal-insurance premiums and gifts or contributions, so that some expenditures of present benefit (utility) to the household are incorporated in the measure of savings. If we adjust the average income profile by subtraction of contributions and insurance at each age, so as to obtain a closer identification of the income-consumption differential with savings, we find that the profile stays just below actual consumption up to age 45, then exceeds it in years beyond. This is perfectly consistent with a pattern of desired consumption in excess of actual in the 25–45 age interval and below actual in later years.

On the other hand, the expected near-equality of desired and actual consumption in zero-saving situations cannot hold irrespective of whether savings are defined to include or exclude certain items. Thurow's liberal offer of a choice between two estimates obtained by applying the same methodology to two definitions of savings weakens confidence in the validity of his sampling.

---

[19] With the a priori specification: $r(50)=0$, the relative wealth W^i under income profile i is obtained as $y^i_{50}/\bar{y}_{50}$, where y^i_A is profile i income at age A and $\bar{y}_A$ is average income at age A. If the profiles behave in accordance with (19′) without error, we have:

$$y^i_A = W^i[\bar{y}_A + r(A)] - r(A)$$
$$r(A) = \frac{y^i_A - W^i\bar{y}_A}{W^i - 1}$$

The above expression is used to compute three point estimates of $r(A)$—one for each of the three profiles—at each age of observation. The figures shown for each age above are simple averages of the three point estimates.

[20] The plot of actual consumption is that of average consumption under Thurow's "first" definition—exclusive of personal transfers and insurance. The diagram also shows Thurow's own estimate of $g(A)$ under the corresponding definition. Note that the identification of average consumption as the consumption of a household with average income can only be accepted as an approximation.

(27) and (28) becomes $P=1/b$, and the weight of identification falls entirely on the biasing term $\psi(W)$.[16] This should not have prevented Motley and Morley from deriving P by reference to the data at hand, as was done in Section IVA. However, the temptation was strong to utilize external evidence already processed under similar assumptions, namely, estimates of P derived by Milton Friedman in substantiation of his permanent-income hypothesis.[17] Since there is far from unanimous agreement concerning these estimates, the door is open for suggestions that, as Thurow puts it in his uncorrected reply, b (or P) was "judiciously selected" to maximize the error of his identification.[18]

Alternatively, for Thurow to insist that his belated introduction of the absurd relation $W=k^*+\gamma$ for zero savers confirms his model as a legitimate alternative throws doubt on the seriousness of his purpose. But the excessive indirectness of Motley and Morley's evidence may have helped fortify the impression that they were introducing an "alternative model" to Thurow's, when in fact they were providing a necessary complement to Thurow's initial structure to make the identification of $g(A)$ possible.

D

The tilting term $r(A)$ in the equation of income profiles was neglected in the previous sections, to accord with Motley and Morley's assumptions. With its reintroduction, equations (19) and (23) become:

$$(19')\quad \hat{y}_A = f(A)W - r(A)$$

$$(23')\quad \mathring{y}_A = [f(A)W - r(A)]\psi_A(Y_A)$$

The reasoning and assumptions of Section IIID lead to the modified expression:

$$(28')\quad \mathring{y}^*_A = G_4(A) = g(A)\,\frac{(1-p)f(A)+pr(A)}{f(A)-pg(A)}$$

The estimate $\hat{g}_A$ at each age of observation is derived from (28′) as

$$(29')\quad \hat{g}_A = \frac{\mathring{y}^*_A[F(A)+r(A)]}{p[y^*_A+r(A)]+(1-p)[F(A)+r(A)]}$$

where $F(A)=f(A)-r(A)$ is the mean income profile. Identification of $g(A)$ thus requires estimates of both p and $r(A)$ in addition to the mean income profile $F(A)$.

With the mean income at age M respecified as $F(M)$, the reasoning of Section IIIE leads to the estimating equation for p:

$$\mathring{c}_M/j(M) = (1-p) + p\,\frac{\mathring{y}_M + r(M)}{F(M)+r(M)}$$

i.e., observed incomes entering the ratios must be corrected by the factor $r(M)$. Since, however, the tilting factor is small in the middle range of the observed life span, the correction can be neglected and the value of p obtained in A can be retained.

---

[16] If, in addition to $H(W)=W$, we also set $\psi(W)=1$, the modified system (22)–(24) reduces to $f(A)/g(A)=\mathring{y}_A/\hat{c}_A=1$, and only determines ordinates of the two points of intersection of mean-income and mean-consumption profiles. The "shrinkage" of the observed consumption distribution in relation to that of income can certainly be explained in terms other than the statistical bias favored by proponents of the permanent-income hypothesis, i.e., in terms of a parameter e of $H(W)$ significantly different from one, as suggested in Section IIIc. In any case, strong assumptions concerning $H(W)$ are unnecessary for the resolution of the problem at hand.

[17] See Motley and Morley, pp. 740 and 742. Our parameters b and P have the same definition as in their article. Given (19), $h(W)=W$ in (18), and $e=1$, expression (27) reduces to

$$\hat{y}_A = \left(1-\frac{1}{b}\right)f(A) + \frac{1}{b}\mathring{y}_A$$

or

$$\hat{y}_A = (1-P)f(A) + P\mathring{y}_A$$

which is the equivalent of Motley's and Morley's equation (3).

[18] It evidently occurred to Thurow that Motley and Morley's equation (7), to which he refers in the uncorrected reply, can be read as $\mathring{\hat{y}}^* = (P-1)\overline{C}_t/(\gamma_t P-1)$ where $\overline{C}_t$ is our $g(A)$ and γ_t is $g(A)/f(A)$. The equality of $\mathring{\hat{y}}^*$ and $\overline{C}_t$ can only occur for $P=0$, and the bias of $\mathring{\hat{y}}^*$ as an estimate of $\overline{C}_t$ increases with the size of P. However, $P=0$ carries the absurd implication that a family's expected income and consumption at any given age are independent of its lifetime earnings, i.e., are equal, respectively, to average income and consumption.

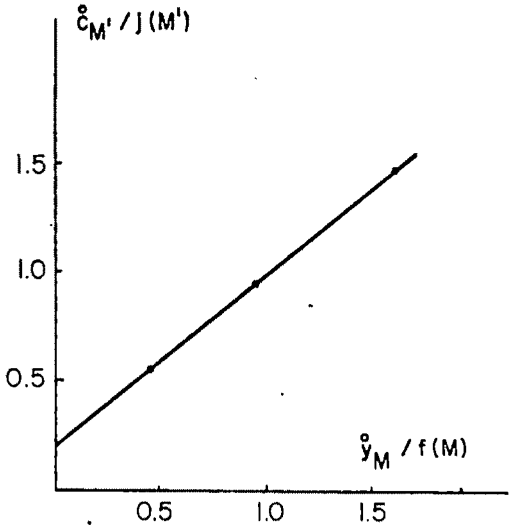

FIGURE 4

$$\overset{\circ}{c}_M/j(M) = 0.20 + 0.80\overset{\circ}{y}_M/f(M)$$

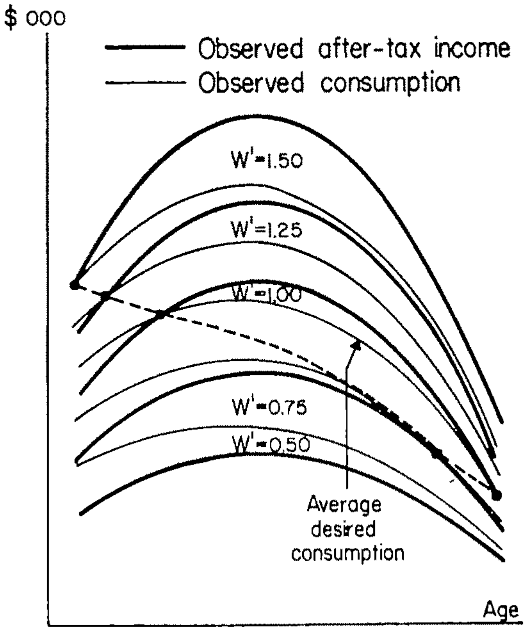

FIGURE 5. SIMULATION OF THUROW'S ESTIMATE

Introducing $p=0.80$ and *BLS* measures of $f(A)$ in relation (29), we obtain the estimate of $g(A)$ already calculated through an equivalent formula by Motley and Morley, p. 742, Figure 3. Comparison with the average profile of actual consumption suggests that discrepancies between desired and actual consumption are extremely minor and do not justify demands for drastic reform of *U.S.* lending policies as they affect younger age groups.

B

While the estimate of p presented in Section IVA may be questioned, it certainly reassures one that p is nowhere near zero. The fact of a considerable bias in Thurow's estimate of the desired-consumption profile is thus beyond question. For a visual illustration of its occurrence, a set of observations $\overset{\circ}{y}_A^*$ is graphed in Figure 5 under hypothetical specifications of the model. Starting with dome-shaped functions $f(A)$ and $g(A)$ describing $\overset{\circ}{y}_A$ and d_A as functions of A for $W=1$ and assuming $j(A)=g(A)$, we obtain four additional sets of observed income and actual consumption profiles for values of $\overset{\circ}{y}_A/f(A)=W'=0.50$, 0.75, 1.25, and 1.50. The $\overset{\circ}{y}$ profiles are obtained through direct multiplication of $f(A)$ ordinates by W'; the $\overset{\circ}{c}$ profiles are obtained through multiplication of $g(A)$—or $j(A)$—ordinates by $(0.20+0.80\ W')$. The function $\overset{\circ}{y}_v^*=G(A)$ goes through the intersections of each associated $\overset{\circ}{y}$ and $\overset{\circ}{c}$ curve (large dots) and is traced as a thick dotted line through interpolation. It obviously bears little relation to the shape of function $g(A)$.

C

Thurow's easy (if unwarranted) dismissal of similar findings by Motley and Morley can be traced to essentially one point, i.e., their initial assumption that $h(W)=W$ and $\theta(W)=1$, i.e., that the average propensity to consume is constant at each age and (much less significantly) that the biasing term $\theta(W)$ can be neglected. With $H(W)$ thus reduced to W (i.e., $e=1$), the parameter $p=e/b$ in

---

sumption. The assumption, therefore, is that $\overset{\circ}{c}_{M'}/j(M') = d_M/g(M)$ holds approximately true for sets (M, M') in the medium range of the observed life span. This (unnecessary) complication was excluded from the presentation in the text to achieve greater clarity.

$$\mathring{c}_A = g(A)H(W) \tag{25}$$
$$\text{with } H(W) = 1 - e + eW$$

$$\mathring{y}_A = f(A)\phi(W) \tag{26}$$
$$\text{with } \phi(W) = 1 - b + bW; \quad b > 1$$

Reducing (25) and (26) through elimination of W leads to

$$\mathring{c}_A/g(A) = (1 - p) + p\mathring{y}_A/f(A); \qquad p = e/b \tag{27}$$

and, in view of (24),

$$\mathring{y}^*_A = G_1(A) = g(A)\frac{(1 - p)f(A)}{f(A) - pg(A)} \tag{28}$$

This expression is of the same form as that obtained in Section IIIc with $r(A)=0$ and supports similar conclusions, i.e., the identification of the plot of $\mathring{y}_A$ with $g(A)$ is misleading unless $p=0$, or $e=0$ and $H(W)=1$. This, of course, no longer implies invariance of the desired-consumption profile with lifetime income; with $\theta(W)$ a variable function of W, $H(W)=h(W)\theta(W)=1$ implies that $h(W)$ also varies with W. Since, however, $\theta(W)$ is an increasing function of W, we would have to accept that $h(W)$ decreases as W rises, i.e., that the profile of desired consumption shifts downward as lifetime earnings increase. A correction of the plot to $\mathring{y}^*_A/k$ leads to identification problems similar to those uncovered in Section IIIc.

IV. Alternative Estimates of $g(A)$

A

It is apparent, then, that we must give up on Thurow's estimate. This, however, does not mean that $g(A)$ is beyond identification under proper use of the available information. Accepting the specifications in Section IIID, we can obtain an estimate, $\tilde{g}_A$, of $g(A)$ at each age of observation from (28):

$$\tilde{g}_A = \frac{\mathring{y}^*_A f(A)}{p\mathring{y}^*_A + (1 - p)f(A)} \tag{29}$$

All we need is an estimate of parameter p and a measure of average income, $f(A)$, at each age.

The reader is again referred to Figure 3 in which the *BLS* data available to Thurow were used to plot income and average consumption at the 10th, 50th, and 90th percentiles of the income distribution, for available age intervals. As a first step toward estimating p, write expressions (18) and (19) for the desired consumption and expected income of age M households with observed income and consumptions $\mathring{y}_M$, $\mathring{c}_M$:

$$d_M = g(M)h(W) \quad \text{and} \quad \hat{y}_M = f(M)W$$

and suppose that we expect $\hat{c}_M/j(M) = d_M/g(M)$, where $j(A)$ is average actual consumption as a function of age. The condition states that at age M intended consumption relative to its average is equal to desired consumption relative to its average.

The system above can then be written

$$\hat{c}_M = j(M)h(W) \quad \text{and} \quad \hat{y}_M = f(M)W$$

and the observed magnitudes, in view of (16) and (17), satisfy:

$$\mathring{c}_M = j(M)H(W) \quad \text{and} \quad \mathring{y}_M = f(M)\phi(W)$$

In correspondence with expression (27), we obtain

$$\mathring{c}_M/j(M) = (1 - p) + p\mathring{y}_M/f(M) \tag{30}$$

allowing p to be estimated by reference to several sets of observations of $\mathring{c}_M/j(M)$ and $\mathring{y}_M/f(M)$.

We assume that $\hat{c}_M/j(M) = d_M/f(M)$ holds approximately true in the medium range of the observed life span, and we arbitrarily set M at the age of maximum average income. Three sets of magnitudes ($\mathring{c}_M$, $\mathring{y}_M$) are thus determined by reference to the three sets of profiles in Figure 3, and the three corresponding sets $[\mathring{c}_M/j(M), \mathring{y}_M/f(M)]$ are obtained after reading average income and average consumption at age M from *BLS* tabulations (also the source of identification of M).

The three sets of ratios are plotted in Figure 4. The linear fit is almost perfect in the relevant range,[15] and we find:

---

[15] The ratios shown are based on measures of consumption at the age, M', of maximum average con-

D

A more careful reading of the empirical context does suggest, however, that conditions (2) or (11) as written are not relevant. As noted by Motley and Morley, Thurow does not have access to individual observations of zero-saving families. Rather, he obtains from Census sources large-sample averages of actual consumption expenditures and after-tax income for successive income intervals at different ages. It is well known from the "permanent income" literature that in the year of observation, households of age A with observed income and consumption $\overset{\circ}{y}_A$ and $\overset{\circ}{c}_A$ expect on the average an income $\hat{y}_A$, and intend a consumption $\hat{c}_A$, which differ from $\overset{\circ}{y}_A$ and $\overset{\circ}{c}_A$. The differences reflect the presence of "transitory" components of income and they are respectively related to the ratios $Y_A=\hat{y}_A/f(A)$ and $C_A=\hat{c}_A/j(A)$, where $f(A)$ and $j(A)$ are the income and consumption of an average family at age A.

Specifically:

$$(16) \qquad \hat{c}_A = \overset{\circ}{c}_A/\theta_A(C_A)$$

$$(17) \qquad \hat{y}_A = \overset{\circ}{y}_A/\psi_A(Y_A)$$

the functions $\psi_A(Y_A)$ and $\theta_A(C_A)$ increasing respectively with Y_A and C_A and taking value 1 when the variable is one.

Going back to the argument offered in Section II, it is apparent that statements such that "$d-c\geq 0$ under dissaving," or "actual dissaving cannot exceed desired dissaving," will not hold if *actual* income and consumption refer to observed rather than expected or intended quantities: If a household dissaves more than it intends because of a high negative transitory component of income, it is possible for observed dissaving to exceed the "desired" level. It follows that the proper zero-saving points to select for the purpose of identifying desired consumption are those for which $\hat{y}_A=\hat{c}_A$, where we expect $d_A=\hat{c}_A$. This, however, is not feasible, and we must follow Thurow and others in selecting observations for which $\overset{\circ}{y}_A=\overset{\circ}{c}_A$, or $\hat{y}_A=\hat{c}_A\theta_A(C_A)/\psi_A(Y_A)$, i.e., where intended consumption is different from expected income and, thus, intended saving is different from zero. Specifically, there is intended dissaving where zero saving is observed in the high range of income profiles and intended positive savings on low profiles.[13] We shall nevertheless assume $d_A=\hat{c}_A$ at points of zero observed savings ($\overset{\circ}{y}_A=\overset{\circ}{c}_A$), but as a provisional measure, and the resulting bias of desired-consumption estimates will be discussed in Section IVE.

In determining the possible effect of reinterpreted observations on the validation of Thurow's estimate, there is advantage in simplifying the expression of y_A (or $\hat{y}_A$) by elimination of the "tilting" term $r(A)$. This does not affect the substance of the conclusions, and it brings out strong similarities between this analysis and that of Motley and Morley. Under the new specification, and accepting $d_A=\hat{c}_A$ where zero savings are observed, we are dealing with a simultaneous system that includes (16) and (17) above and:

$$(18) \qquad d_A = g(A)h(W)$$

$$(19) \qquad \hat{y}_A = f(A)W$$

$$(20) \qquad \overset{\circ}{y}{}^*_A = \overset{\circ}{y}_A = \overset{\circ}{c}_A$$

$$(21) \qquad \hat{c}_A = d_A$$

where $\overset{\circ}{y}{}^*_A$ is the zero-saving observation at age A.

This reduces to:

$$(22) \qquad \overset{\circ}{c}_A = g(A)h(W)\theta_A(C_A)$$

$$(23) \qquad \overset{\circ}{y}_A = f(A)W\psi_A(Y_A)$$

$$(24) \qquad \overset{\circ}{y}{}^*_A = \overset{\circ}{y}_A = \overset{\circ}{c}_A$$

Under linear approximation of the terms $h(W)\theta_A(C_A)$ and $W\psi_A(Y_A)$, equations (22) and (23) become:[14]

---

[13] Because of the lesser sensitivity of consumption to transitory components of income, $\theta(C_A)$ increases with C_A much slower than $\psi(Y_A)$ does with Y_A. Writing the approximation $Y_A=C_A=Q_A$, the ratio $\theta_A(Q_A)/\psi_A(Q_A)$ is less than 1 for $Q_A>1$ and more than 1 for $Q_A<1$.

[14] Given the small expected range of $\theta_A(C_A)$, we assume it replaceable by a function $\theta(W)$ common to all ages and introduce the linear approximation $h(A)\theta_A(C_A)=h(A)\theta(W)=1-e+eW$.

We assume the function $\psi_A(Y_A)$ to be common to all ages and well approximated by the simple expression $\psi(Y_A)=1-b/Y_A+b$, $(b>1)$. Since, by (19), $Y_A=\hat{Y}_A/f(A)=W$, we have $W\psi_A(Y_A)=1-b+bW$.

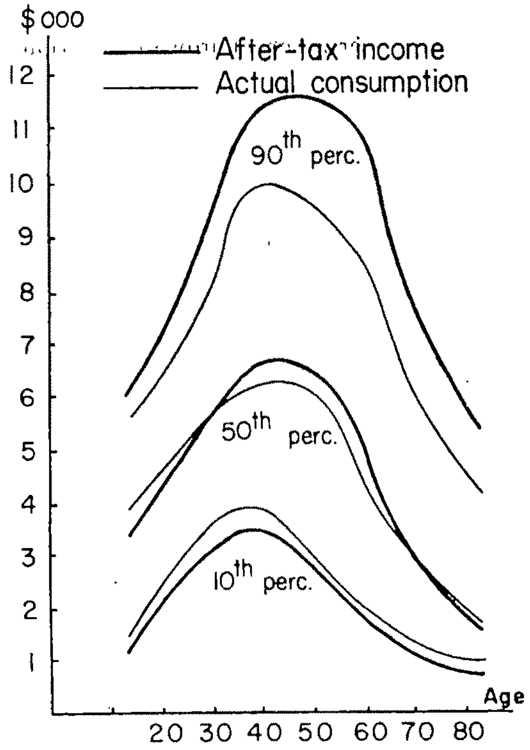

FIGURE 3. *BLS* DATA

Another is that intergenerational savings increase with lifetime earnings.[10]

Accordingly, we respecify the system developed in Section IIIB as follows:

$$d_A = g(A)h(W) + \eta \tag{9}$$

where η is independently distributed with mean zero, and the scaling factor $h(W)$ now appears as a function of W taking value 1 for $W=1$;

$$y_A = f(A)W - r(A) + \epsilon \tag{10}$$

where ϵ is independently distributed with mean zero, which simply reproduces expression (6).

Continuing to treat Thurow's measures as large-sample averages of individual observations, y_A^*, we retain (2) and (3) as:

$$\overset{*}{y}_A = y_A = c_A \tag{11}$$

$$d_A = c_A \tag{12}$$

Assuming $h(W)$ to be of the simple form[11]

$$h(W) = (1 - a) + aW \tag{13}$$

reduction of the system by elimination of W leads to:

$$\overset{*}{y}_A = G_2(A) + \zeta_2 \tag{14}$$

where

$$G_2(A) = g(A)\,\frac{(1 - a)f(A) + ar(A)}{f(A) - ag(A)} \tag{15}$$

$$\zeta_2 = \frac{\eta f(A) - \epsilon a g(A)}{f(A) - ag(A)}$$

Since ζ_2 is distributed with mean zero at each age, the plotting of a large-sample mean of y_A^* observations at successive ages will provide a correct estimate of $G_2(A)$. Again, however, the latter expression bears little resemblance to the function $g(A)$ sought by Thurow. It will only be equal to it if $a=0$; i.e., if $h(W)=1$. A correct identification of $g(A)$ with the plot would thus require that desired consumption be totally independent of lifetime income.

If, in more precise agreement with Thurow, the identification is with $\bar{y}_A^*/k$, we require:

$$g(A) = \frac{1}{k}\left[f(A)\,\frac{k - 1 + a}{a} - r(A)\right]$$

While we may accept an a priori specification of $g(A)$ in this form (with k treated as an unknown), we find that the equality of y_A and d_A at zero-saving points implies $y_A = f(A)h(W) + \epsilon'$, in which case zero-saving observations identify vertical lines at the intersection of $g(A)$ and $f(A)$ rather than the desired function $g(A)$.[12]

---

[10] Another possible bias is linked to intergenerational transfers: Low-income earners may receive more than their share of unreported parental gifts and free parental services.

[11] Equations (9) and (13) are consistent with explicit assumptions in Thurow's initial article, and with his "Erratum" statement to the extent that a is allowed to take value 1 and thus regenerate the system of Section IIIB.

[12] Replacing $g(A)$ by the proposed expression in (9), and writing $d_A = y_A$ (error terms excluded), reduction leads to $r(A) = f(A)(a-1)/a$.

ifications, we write:

$$y_A = f(A)W - r(A) + \epsilon \tag{6}$$

where ϵ is independently distributed with mean zero, which adequately describes the range of conceivable relations between income profile and wealth. The term $r(A)$ allows a "tilting" of the expected income profiles as a function of W, as suggested by observation (see Section IVD).

Joining equation (6) with (1), (2), and (3) specified in Section IIIA, i.e., replacing (4) by (6) in the original simultaneous system, reduction of the system by elimination of W leads to:

$$y^*_A = G_1(A) + \zeta_1 \tag{7}$$

where

$$G_1(A) = \frac{g(A)r(A)}{f(A) - g(A)} \tag{8}$$

$$\zeta_1 = \frac{\eta f(A) - \epsilon g(A)}{f(A) - g(A)}$$

Since ζ_1 is distributed randomly with mean zero at each age, the plotting of a large-sample mean of y^*_A observations at successive ages will provide a correct estimate of $G_1(A)$—and a homothetic adjustment of the plot by some factor $1/k$ will provide an estimate of $G_1(A)/k$. Clearly, the latter expression need not bear any resemblance to the function $g(A)$ sought by Thurow. In order to get $G_1(A)/k = g(A)$, we need:

$$g(A)r(A) = kg(A)[f(A) - g(A)]$$

or

$$g(A) = f(A) - r(A)/k$$

No relation of this type is assumed by Thurow, although the specification of $g(A)$ as a tilted version of $f(A)$, i.e., $g(A) = f(A) - r(A)/k$, k unknown, would not be totally unreasonable. However, the procedure is doomed by the fact that the equality of income and consumption at the observation points would either require a priori specification of W as equal to estimated k for all zero savers (which leaves us exactly where Thurow is) or impose elimination of the term $r(A)$ (in which case $g(A)$ is set identical to $f(A)$).[7] It is apparent that the discovery of a structure under which Thurow's estimation procedure would be proper requires the expenditure of some more subtlety.

C

In a further attempt at justifying Thurow, the reader is referred to Figure 3 in which the *BLS* data available to Thurow were used to plot average income and average actual consumption at the 10th, 50th, and 90th percentiles of the income distribution, for available age intervals.[8] It is apparent that the spread of consumption profiles is narrower than that of income profiles, i.e., that the overall level of consumption rises less than proportionately with the overall level of income.[9] While much of this "shrinkage" may represent a measurement bias attributable to averaging effects (see Section IIID), one possible explanation is that households with high lifetime earnings keep underestimating future income, and those with low lifetime earnings tend to overestimate future income.

---

[7] For zero savers, the equality of nonstochastic elements of y_A and d_A, as specified, implies:

$$f(A)W - r(A) = W[f(A) - r(A)/k]$$

$$r(A)\left(\frac{W}{k} - 1\right) = 0$$

$$r(A) = 0 \quad \text{or} \quad W = k$$

If we follow Thurow's practice of measuring lifetime incomes as simple sums of annual incomes over life, we must have $\sum r(A) = 0$ over the observed life span. With this specification and $W = k$ for zero savers, the system determines the unknown parameter k as Thurow's k^*.

[8] I am indebted to William Spaeth and Robert Gough for estimating these profiles from Thurow's sources. Spaeth's exploration of the data suggests that the identification of zero-saving income in each age group is far from unambiguous, and that the measures of after-tax income and consumption expenditure may suffer from serious biases, variable with age and income. For instance, the account-balancing difference in the younger age groups averages 5 percent of reported after-tax income.

[9] The overall excess saving revealed by the figure results primarily from the adoption of one of Thurow's two definitions of consumption, i.e., one that excludes insurance premiums and charitable contributions and, thus, formally incorporates the latter into savings. This definition is adhered to up to section IVE of the paper, when appropriate corrections are made.

come (zero actual saving). If we call y_A^* the income of a zero-saving family at age A, the observational constraint leads to the simultaneous condition:

$$\overset{*}{y_A} = y_A = c_A \tag{2}$$

where y_A is income and c_A actual consumption of the family.

Two additional conditions are introduced simultaneously with (1) and (2):

(a) For zero savers, desired consumption is equal to actual consumption:

$$d_A = c_A \tag{3}$$

(b) The lifetime income of zero savers is randomly distributed around some constant, i.e., the ratio of their lifetime income to average lifetime income is given by:

$$W = k^* + \gamma \tag{4}$$

where γ is independently distributed with mean zero. The constant k^* is defined and calculated as the ratio of summed averages of y_A^* observations in each age interval to summed averages of incomes in each age interval.

Reduction of the system (1), (2), (3), and (4) by elimination of W leads to:

$$\frac{\overset{*}{y_A}}{k^*} = g(A)(1 + \gamma') + \eta' \tag{5}$$

where $\gamma' = \gamma/k^*$ and $\eta' = \eta/k^*$ are independently distributed with mean zero.

If the above specification is correct, the plotting of $\bar{y}_A^*/k^*$ where $\bar{y}_A^*$ is a large-sample mean of observations y_A^* in age interval A should provide a correct estimate of $g(A)$. This indeed is the way in which Thurow obtains his estimate of $g(A)$, although, as indicated in Section IIID, the average income of zero savers which he measures at each age differs from $\bar{y}_A^*$.

Of the two conditions holding under zero saving, only the first, (3), is fully verbalized and justified by Thurow. The second, (4), is eventually made explicit in the "Erratum" contribution (Thurow's equations (1) and (2)), but never justified. This is sensible enough given the difficulty of the undertaking:[5] The notion that families found in a zero-saving situation at any age are all hovering around a level of lifetime income peculiar to them is, indeed, difficult to swallow. It is not inconceivable that some special form of the relation between income profiles, consumption profiles, and lifetime income could result in zero savers enjoying a common (expected) level of wealth. However, Thurow never describes with less than considerable ambiguity what income profiles occur at different levels of life-wealth,[6] and he does not, in any case, seem overly concerned by the oddity of condition (4).

While the hope of justifying condition (4) is too thin to pursue, we may, at least, attempt a check of whether any reasonable specification of the profiles could generate an estimation of $g(A)$ as $\bar{y}_A/k$, where k is a constant that may or may not equal k^*. Such an attempt is made—without success—in the next three sections, drawing on weak empirical information available from the *BLS* data.

B

As a first step in exploring promising spec-

---

[5] Motley and Morley make this point with great clarity, concluding that Thurow's procedure ". . . is valid only under the unstated (and almost certainly false) assumption that the lifetime income of the *zero-savers* is the same in every age group" (p. 739). In his original response, Thurow (1970) faults Motley and Morley for missing the assumption in his article. He calls attention to his assumption (2), and points out, p. 745, that he identified the bias likely to result from its dubious status. Assumption (2), however, merely states ". . . that individuals in older age brackets are similar in all relevant aspects with those in younger age brackets" (p. 326), and it refers to the fact that the average growth of earnings over time implies different lifetime earnings for individuals of different ages found to have the average income for their age in the year of observation. The assumption that such differences do not exist has, obviously, nothing to do with the assumption relating to zero savers, and Thurow's reference to it misses the point altogether.

[6] An unwary reading of Thurow's first article does yield a near-explicit assumption concerning income profiles and life-wealth; namely, that income profiles are derivable for one another by homothetic transformation in proportion to lifetime income (W). The context suggests, however, that the statement may refer instead to desired-consumption profiles in accordance with (1) above.

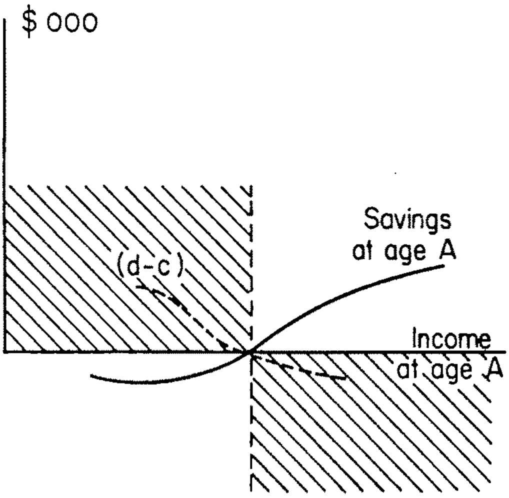

FIGURE 1

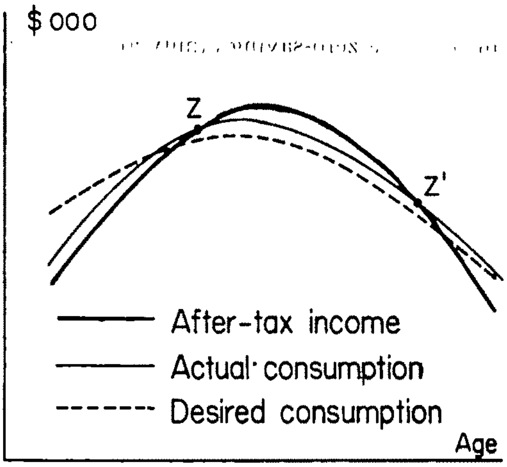

FIGURE 2. ILLUSTRATIVE PROFILES

age-profile of income, dissaving is at first rationed then becomes freely adjustable, actual consumption must rise with income until it reaches desired consumption, then continue up *above* the desired-consumption profile in view of the "excess" net assets created by former restrictions on dissaving. As illustrated in Figure 2, the intersection of actual consumption with income (zero saving) will generally occur above the desired consumption profile. The discrepancy (the excess of c over d at zero-saving point Z) depends on the extent of foregone dissaving in the earlier period and on the manner in which the household distributes additional consumption over the remainder of its life. Similarly, the zero-saving point Z' occurring later in life as income falls back may represent a consumption above the desired level if credit restrictions were effective in earlier years.

Short of developing more ambitious models, the selection of zero-savings observations can only be defended on the grounds that it guarantees a consistently positive bias of the desired-consumption measure, that this bias is likely to be smaller at the relatively low consumptions achieved at Z and Z' than in the peak period in between, and that, a posteriori, estimated desired consumption (when proper estimating methods are used) exceeds actual consumption by only small amounts and relatively late in the life cycle, thus assuring us that the biasing effect of foregone dissavings is weak over most of the profile.

III. A Case of Misidentification

The main contention of this review is that Thurow's analysis incorporates a fundamental error of identification, with the result that the estimated pattern of desired consumption represents nothing of the sort.

A

Although the precise nature of Thurow's assumptions remains clouded, he is quite specific in his last "Erratum" contribution concerning the relationship of desired consumption to lifetime income; i.e.,

$$d_A = g(A)W + \eta \tag{1}$$

where η is independently distributed with mean zero, d_A is desired annual consumption of the family at age A, $g(A)$ gives d_A as a function of age for a family of average lifetime income, and W is the family's lifetime income in relation to the average. Not only, then, are desired-consumption profiles at different levels of lifetime income obtainable from one another through homothetic transformation, but the proportionality factor is W itself.

Observations are constrained to situations in which actual consumption is equal to in-head are found by moving down the array of incomes at each age interval and stopping when saving (after-tax income *minus* consumption expenditure) falls to zero. The consumption expenditure (or after-tax income) thus identified is taken as the desired consumption of the average family when the age of its head is at the midpoint of the age interval. This procedure allows the estimation of as many points of the relationship as there are age intervals, and the remainder of the curve is obtained through interpolation. Thurow's plot of desired consumption is reproduced in Figure 6, where it can be compared with the actual-consumption profile.

The above procedure is justified by a seemingly obvious proposition: While people may be prevented from dissaving, there is no institutional constraint on saving, so that the after-tax income at which households in any age class show zero savings must represent the "desired" consumption expenditure of the average household at that age. A second look forces one to conclude that the statement can only be true of zero-saving households in the age class, not necessarily the "average" household. Further thinking suggests that by the reasoning offered, the observed consumption of households in a positive-saving situation should also be equal to its desired level. Finally it is not altogether clear that zero saving does imply equality of observed and desired consumption. Thurow recognizes these and other difficulties with his approach. One of them leads him to modify the estimate described in the previous paragraph: As the lifetime income of zero savers turns out to differ from the average, the curve is scaled along the consumption dimension so that aggregate desired consumption over life is equal to aggregate after-tax income. Overall, however, Thurow leans toward the position that the various problems he identifies do not seriously weaken his main conclusions, and their further elaboration by reviewers of his article leaves him undisturbed.

II. A Justification for the Zero-Saving Sample

Since both Thurow's analysis and the modifications proposed further down are based on the selection of zero-saving observations, some evaluation of the limits of validity of such a sample is in order.

If we designate actual consumption by c and desired consumption by d, we can state in the first approximation:

$d - c \geq 0$ if observed savings are negative

$d - c \leq 0$ if observed savings are positive

The first statement follows from the fact that nothing can force an individual to dissave more than he judges appropriate in the light of prospective incomes and interest rates, but that institutional borrowing restrictions may force him to dissave less (consume less) than what he perceives as optimum. The second statement follows from the observation that if desired dissaving has been thwarted in the first stage of life because of borrowing restrictions, the net asset position of the household has been increasing over its desired level (i.e., over the level achieved when dissaving proceeds optimally by reference to income and interest prospects), and the level of consumption selected in the later "saving" stage of the life cycle is higher (at any age, no less) than the level chosen under ever-perfect credit conditions. In other words, actual consumption may exceed desired consumption when observed savings are positive.

For successively higher household incomes at some given age, the rising curve in Figure 1 illustrates the change in savings. The shaded areas describe the field of possibilities for $(d-c)$ in accordance with the statements above. If in addition we assume that $(d-c)$ varies continuously with household income at the given age, the $(d-c)$ curve must cross the ordinate at the zero-saving point, i.e., zero-saving households are the only ones for which the equality of d and c is guaranteed. This presumably is Thurow's justification for his choice of observations, although his own formulation is excessively cryptic.

Unfortunately, the statements relating the sign of $(d-c)$ to that of savings do not hold strictly, as both Thurow and his critics have recognized. Assuming that in the typical

The Optimum Lifetime Distribution of Consumption Expenditures: Comment

By ANDRE DANIERE*

Two reviewers have already had a hand at exposing grievous errors in Lester Thurow's article concerned with the optimum consumption profile over life.[1] As will be recalled, Thurow attempted to estimate the pattern of consumption over life which the "average" family would select in the absence of institutional contraints on dissaving. This is the consumption pattern it would choose when faced with a given lifetime income and a rate of interest at which it may borrow or lend. Thurow finds such a pattern of consumption (which he calls *desired* consumption) to be substantially at variance with both the pattern of income and that of actual consumption over time, desired consumption (in the sense given) far exceeding actual consumption in early years. Thurow (1969) concludes:

> Based on the results of this analysis, lifetime welfare levels might be substantially increased if the constraints on lifetime income redistribution [mainly, constraints on long-term consumption borrowing] could be lifted. Consequently social planners should investigate methods of eliminating the institutional constraints. [p. 329]

Careful readers of the critical review offered by Brian Motley and Samuel Morley will be left in no doubt that the estimate of the desired-consumption profile offered by Thurow is wide of the mark—or, at the very least, that it bears no necessary relation to the curve he sought. There is evidence, however, that the too comprehensive and yet incomplete attack mounted by the reviewers, together with its airy dismissal by Thurow,[2] have left the average reader convinced of the essential validity of Thurow's conclusions. His results have already found their way into at least two recent reports concerned with loans to college students;[3] other sweeping proposals are likely to draw support from the new findings, possibly going all the way to subsidization of early-consumption loans (to make up for presumed attitudinal or informational handicaps of the young) at the cost of more worthy investment alternatives. There is thus some value in belaboring the point that Thurow's findings are misleading, this time concentrating on the least debatable and most damaging of his errors and calling it by its name; i.e., a classical case of misidentification. As a by-product, alternative estimates of the "desired-consumption" profile can be derived, taking advantage of Thurow's insights and refining the work of earlier reviewers.

I. Outline of Thurow's Estimation

The method of estimate used by Thurow is attractively simple and can therefore be described in simple form. His data base consists of survey figures showing average money income after taxes and average current consumption expenditure of families for different age-of-head and money-income intervals.[4] Points of the curve relating desired consumption of the average family to age of its is useless in any case, since the estimation of option price is no more difficult than the estimation of expected consumer's surplus. This assertion can be answered by a counterexample that indicates the sort of applied analysis I had in mind.

[4] See U.S. Bureau of Labor Statistics (*BLS*), Tables 14a–14g.

If one is concerned with the benefits attainable by preserving a wilderness area for recreational uses, a logical procedure if income effects are small is to estimate the aggregate demand curve for the area and to compute an aggregate surplus measure from it, a procedure followed by, for instance, John Krutilla et al. Since there are inevitably uncertainties attached to the level and shape of future demand functions, this approach yields, at best, aggregate expected consumer's surplus. I was concerned with the question of whether such a benefit measure should be scaled up because some of the associated uncertainty derives from the uncertain future preferences of potential demanders. My analysis indicates that, indeed, aggregate expected surplus is not a perfect measure of aggregate option price, the quantity one would most like to know. But, since I further showed that the bias (aggregate option value) can be of either sign, there is no general case for scaling up expected surplus estimates because preferences are uncertain. My suggestion amounted to the recommendation that such estimates be used without adjustment for this source of risk. Nothing in Bohm's comment has persuaded me to withdraw it or to make any other substantive alteration in my paper.[6]

---

[6] I would, however, strike the assertion that my definition of risk aversion is the "usual" one. Bohm's comment and a perusal of various texts and standard references have convinced me that no such definition exists.

possible states of nature, the U^i are the conditional indirect utility functions, the Y_i are the conditional incomes, and P is the vector of state-independent prices. Given (1), Bohm would prefer to say that the consumer is risk averse if and only if the U^i are all strictly concave in income, so that his definition relates directly to attitudes or preferences.[2] My Theorem 1 shows that a consumer who is risk averse in Bohm's sense will generally accept some fair gambles; this behavior can be ruled out only by also requiring the conditional marginal utilities of income, the U^i_y, to be equal at the point considered.

Thus, for example, even if the U^i are identical and strictly concave in income, the consumer will refuse all fair gambles if and only if the Y_i are also equal. Whether or not a consumer will agree to accept a particular gamble depends both on the structure of his preferences and on the sorts of risks he is bearing initially.[3] This point is easily made in the state preference framework, and, given the incompleteness of real-world contingent commodity markets, it is important in practice.

As I have indicated above and as Bohm's demonstration makes clear, my results do not depend on how risk aversion is defined, so that there is nothing to be gained in this context by arguing that one or the other of our two definitions captures the "true" meaning of the term. Since the word "aversion" has behavioral connotations, though, it might be clearer to use it in connection with my behavioral definition. Some other term, such as "concave preferences," would seem more appropriate to Bohm's attitude-oriented definition.[4]

One further aspect of Bohm's Section I requires a reply. Bohm seems to attach some normative significance to the income/price points considered in my Theorems 2–6, even going so far as to argue that some of them are "inappropriate." This is a confusion. In the absence of a well-specified set of trading opportunities in contingent commodities (such as that analyzed in Section III of my paper, to which Bohm apparently has no objection), there is no reason to expect the U^i_y to stand in any particular relation at any particular point, as Bohm in fact emphasizes. My results simply state that if, for whatever reason, the U^i_y are equal at the indicated points, the sign of option value can be determined. The points considered *were chosen* simply because they have this property, not because there is any welfare-theoretic reason to attach importance to them. Whether the conditional marginal utilities are or are not equal at any one of these points is purely a positive question, a question of fact.

II

Let me now consider Bohm's unhappiness with my suggestion that expected consumer's surplus be used as the best available approximation to option price. He asserts that there is something illegitimate about assuming that preferences can be represented by (1), so that my concept of expected consumer's surplus is not well founded. Formally, however, this assertion has no basis; see R. Duncan Luce and David H. Krantz for a detailed analysis of representations like (1), involving nonidentical conditional utility functions, and of the strong restrictions necessary to force the U^i to be identical.[5] Their work establishes that the state preference approach is indeed applicable to the case of uncertain future preferences.

Second, Bohm asserts that my suggestion

---

[2] Kenneth Arrow (p. 90) defines a risk averter as one *who will refuse* a fair gamble whenever his conditional incomes are equal. When the U_i are identical, this is equivalent to Bohm's definition, but in general it differs from both definitions discussed in the text.

[3] For an interesting analysis that explicitly considers both these elements, see Clifford Hildreth.

[4] I cannot resist making a final point about terminology. The terms "option value" and "option demand" would seem at first glance to have something to do with the value of keeping one's options open, of not reducing the set of possible or plausible actions. Hence, it would seem more natural to employ these terms in connection with option-foreclosing irreversible decisions, such as those considered in the extremely interesting analyses of Arrow and Anthony Fisher, Claude Henry, and Fisher et al.

[5] I am much more sympathetic to the argument that as a matter of fact, most consumer behavior is not sufficiently consistent and clear-headed to be adequately described by expected utility maximization, but that argument is not directly relevant here.

Option Demand and Consumer's Surplus: Reply

By RICHARD SCHMALENSEE*

In his comment, Peter Bohm does not take issue with my principal result, that the sign of option value is generally ambiguous. Rather, he is unhappy with my derivation of this result. In particular, he objects to the way I used the term "risk aversion." His second main objection is to my suggestion that expected values of consumers' surpluses be used as the best available approximation to option prices. I shall answer these in turn.

I

It should be noted at the outset that neither my results nor the proofs used to establish them are called into question by Bohm's comment, and Bohm neither extends nor generalizes my findings. He objects only to my interpretation of these results in terms of risk aversion. Thus the statement at the close of his Section I that option value "may thus be positive, negative or zero, as Schmalensee argued, but not quite for the reasons he chose to give" is totally misleading.

Bohm apparently misunderstands the role of the definition of risk aversion in my analysis. This may be because, as is often the case, the order in which results were presented in my paper did not correspond to the order in which I obtained them.[1] From the definition of option price and the assumed concavity of the conditional indirect utility functions, I was first led to inequalities like his equations (6) and (7) and my (12). As my main goal was to show that the sign of option value is ambiguous, it was necessary to exhibit plausible conditions under which option price exceeded or fell short of expected surplus. Given the relevant inequalities, this is easy, and the conditions simply involve equality of the conditional marginal utilities of income at the income/price points considered in my Theorems 2–6. Since, as Bohm agrees, the conditional marginal utilities may stand in any relation to each other at any point under the assumptions of my analysis, it follows that the sign of option value is ambiguous. Thus, none of the implications of my Section II would have been changed had I replaced "is risk averse" everywhere by "has equal conditional marginal utilities of income." Had I made this change, dropping Theorem 1 and the attendant discussion, I doubt that Bohm would have felt compelled to offer his comment.

In fact, the paper assumed roughly this form in its first draft. I found the presentation unsatisfactory, however, without some indication of the observable consequences, and thus the economic meaning, of having equal conditional marginal utilities of income. Theorem 1 and the association of this equality with risk aversion arose from the search for such consequences. This theorem provides an economic interpretation of the hypotheses of my Theorems 2–6, and it also points up the important distinction between attitudes toward risk and behavior under risk.

I considered a consumer to be risk averse at some income/price point *if and only if he* would refuse all fair gambles at that point, so that my definition relates directly to behavior. This is precisely the definition (of "preference for certainty") given in Section 3 of the pioneering study of Milton Friedman and Leonard J. Savage. Suppose now that the consumer's preferences can be represented by the indirect utility function

$$(1) \qquad V(Y_1, \ldots, Y_N; P) = \sum_{i=1}^{N} \Pi_i U^i(Y_i, P)$$

where the Π_i are the probabilities of the N

---

* University of California, San Diego.

[1] I realize that very little interest, if any, attaches to the manner in which I wrote the paper in question. I discuss it only because Bohm seems to infer, probably from the structure of that paper, that my main interest was in the effects of risk aversion, and this is simply not true.

II

Given that option price may deviate from the expected consumer's surplus in one direction or the other, it may still be argued—as Schmalensee does—that the expected consumer's surplus is the best or even the only approximation to the option price that is available. Now, to calculate the expected consumer's surplus, the decision maker needs to know in principle both the set of π_i for each consumer and the individual consumer's surplus in each state. The decision maker can hardly be expected to be clairvoyant enough to know the π_i, and there is no market behavior to study that reveals these probabilities. In addition, the SC_i is something the decision maker might not be able to find out about. Estimating the consumer's surplus entails the same well-known problems as measuring other access values such as the *WTP* for (access to) public goods—or *OP*, for that matter. Thus, from a practical viewpoint estimating *OP* does not add any new dimensions to the measurement problems that always exist for cases where an estimate of the consumer's surplus is required.

We just argued that it may be difficult for the government to estimate the π_i for each consumer. This is actually a superfluous argument, as we shall now question the relevance of Schmalensee's assumption that the π_i may be known to anyone. It is, as we have seen, different preference functions that constitute the different states. Thus, one state may be characterized by, say, a sudden whim to travel to Yellowstone National Park next summer—to take Schmalensee's illustration. The remarkable thing about this consumer who does not know what he wants to do next summer is that he is capable of knowing and specifying (a) the complete set of his alternative preferences next summer, and (b) the (approximate) probabilities of these alternatives.

Rejecting this assumption as being unrealistic, it is no longer possible to determine the expected consumer's surplus as defined here ($\Sigma\pi_i SC_i$). The option price is therefore the *only* measure of the benefit side of the investment that can conceivably be determined—by sales of access rights, by interviews, by government "introspection," or other imperfect approaches.

III

To sum up, I can agree with Schmalensee's results, given his state-preference approach, on the following points: (a) option values may be either positive or negative in the presence of uncertain future preferences and risk aversion; (b) there may be nonzero option values also in the presence of risk neutrality. However, Schmalensee reached these conclusions on the basis of a definition of risk aversion that I cannot accept. In particular, I have argued that the relevant definition of risk aversion does not require that the U_y^i be identical in all states.

But, more important, I have argued that Schmalensee's state-preference approach is not applicable to the case of uncertain future preferences. As to Schmalensee's remark that " . . . the expected value of the consumers' surpluses ought to be employed as the best available approximation to the sum of their option prices . . . " (p. 823), I have pointed out (a) that it overlooks the fact that the estimation problems are essentially the same for option prices and consumers' surplus, and (b) that there is no information available to the decision maker about how to calculate the *expected* value of the consumers' surplus. Schmalensee's concluding remark that " . . . there would appear to be no practical way to obtain superior estimates" (p. 823) simply has no support in his analysis, as he has not dealt with the practical problems of how to estimate option prices, consumer's surplus, and similar kinds of access values, given that there is no market solution to the problem.

willing to pay for access to the commodity in question at a given price, ***given which state, i.e., preference function, holds.*** But the U_y^i certainly does affect OP, as OP is the maximum price the consumer is willing to pay "today" in order to have access to the commodity at the given price ***in all conceivable "future" states.*** And in the latter case it is naturally relevant to take into account how income changes are valued in the various states. Leaving the U_y^i out would be as if an exporter selling at a given future price in foreign currency did not care about the fact that exchange rates differ in different states.

(b) *Strictly concave U^i functions (risk aversion):*

$$OP > SC_{OP}^{w}$$

If the U^i instead are strictly concave functions, the option price will be larger than the right-hand side in (6) and smaller than the right-hand side in (7). The reason why (6) gives an underestimate and (7) an overestimate of OP is clear from looking at (3′)–(5). Equation (3′) as it stands determines OP; the SC_i are given by (1), and all other variables (except OP) are exogenous. Then, introducing the inequalities (4) and (5) into (3′), we obviously get a lower limit and an upper limit to OP, respectively.

Having said this we may drop (7) out of the picture. The interesting expression is (6) where U_y^i is taken at the point from which the consumer makes his evaluation. Remember that we are asking him how much he can abstain from today in terms of an OP and enter the future state, whatever it may be, with a disposable income of $Y-OP$, without being worse off. He will be at $Y-SC_i$ only if he does not pay an option price—and that is another story. We do not ask him about the maximum amount he is willing to pay provided he does *not* pay that amount.

(c) $OP \gtreqless \Sigma\pi_i SC_i$

What is the relationship between SC_{OP}^{w} in (6), the weighted expected consumer's surplus, and the expected consumer's surplus, $\Sigma\pi_i SC_i$? We know that they are equal when $U_y^i = U_y^j$ for all i and j. The same is true for another special case, viz., $SC_i = SC_j$ for all i and j. In such cases, OP equals or exceeds $\Sigma\pi_i SC_i$ depending on whether the U^i are linear or strictly concave as shown by Schmalensee. In general, however, this relationship does not hold, as we have already pointed out. We may give an example where $\Sigma\pi_i SC_i$ is smaller than SC_{OP}^{w}, and hence, where $OP > \Sigma\pi_i SC_i$ regardless of the alternative shapes of the U^i functions. Take the two-state case where $\pi^1 = \pi^2 = 1/2$ and where $SC_2 = 0$, i.e., where the commodity in question would not be demanded in state 2. (This is the case analyzed by Cicchetti and Freeman.) Thus, for

$$SC_{OP}^{w} = \frac{\Sigma\pi_i SC_i U_y^i}{\Sigma\pi_i U_y^i} = \frac{1/2\, SC_1 U_y^1}{1/2\,(U_y^1 + U_y^2)}$$

$$> \Sigma\pi_i SC_i = 1/2\, SC_1$$

we have that $\quad U_y^1 > 1/2\,(U_y^1 + U_y^2)$

or that $\quad U_y^1 > U_y^2$

It is quite possible of course that this requirement is fulfilled. The same is true for the opposite, i.e., $U_y^1 < U_y^2$, which would mean that $OP \geq SC_{OP}^{w} < \Sigma\pi_i SC_i$. In a case such as this, OP may be smaller than $\Sigma\pi_i SC_i$ (for example, when the U^i functions are linear).

Thus, we have that $OP \gtreqless \Sigma\pi_i SC_i$. If the difference between the two sides is defined as an *option value*, it may thus be positive, negative, or zero, as Schmalensee argued, but not quite for the reasons he chose to give. Schmalensee actually argues that the sign of the option value in the presence of risk aversion depends on whether the U_y^i are measured at $Y-OP$ or at $Y-SC_i$; as we have already pointed out the latter point of measurement is not relevant. (Given Schmalensee's definition of risk aversion and given the consumer's surplus defined as the compensating variation, the sign is actually unambiguously determined as nonnegative.) As we have shown here, the sign of the option value is indeterminate and depends on the relationship between the U_y^i in the different states.

$$(3') \quad \Sigma\pi_i[U^i(Y - OP, P^*) - U^i(Y - SC_i, P^*)] = 0$$

Let us assume that U^i is a concave function so that, in particular,

$$(4) \quad U^i(Y - OP, P^*) - U^i(Y - SC_i, P^*) \geq (SC_i - OP)U^i_y(Y - OP, P^*)$$

$$(5) \quad U^i(Y - OP, P^*) - U^i(Y - SC_i, P^*) \leq (SC_i - OP)U^i_y(Y - SC_i, P^*)$$

Equation (4) inserted into (3′) gives

$$\Sigma\pi_i(SC_i - OP)U^i_y(Y - OP, P^*) \leq 0$$

or

$$(6) \; OP \geq \frac{\Sigma\pi_i SC_i U^i_y(Y - OP, P^*)}{\Sigma\pi_i U^i_y(Y - OP, P^*)} (\equiv SC^w_{OP})$$

and (5) inserted into (3′) gives

$$(7) \; OP \leq \frac{\Sigma\pi_i SC_i U^i_y(Y - SC_i, P^*)}{\Sigma\pi_i U^i_y(Y - SC_i, P^*)} (\equiv SC^w_{SC_i})$$

(SC^w_{OP} and $SC^w_{SC_i}$ stand for the weighted expected consumer's surplus at $Y-OP$ and $Y-SC_i$, respectively). Schmalensee concentrates on the cases where the U^i_y in (6) *or* U^i_y in (7) are the same for all states. (Cicchetti-Freeman make a similar assumption.) If so, the right-hand side becomes $\Sigma\pi_i SC_i$. Hence, OP is either $\geq$ or $\leq \Sigma\pi_i SC_i$, depending on at which point the U^i_y are equal for all i.

Now, it is difficult to see that this type of equality has any particular interest other than as a possible special case. (In spite of the emphasis in Schmalensee's analysis, this seems to be his opinion as well.) What constitutes different states in this problem are different preference functions; hence, as there are no bounds on "how much" they may differ, it may be considered natural that they differ also with respect to U^i_y at any particular point such as $(Y-OP, P^*)$.

The reason why Schmalensee deals almost exclusively with the special case just mentioned is that he wants to find out about the effects of risk aversion and argues that risk aversion exists at a given point, for example, $(Y-OP, P^*)$, if and only if the U^i_y are the same at that point. His definition of risk aversion may be questioned, however. Schmalensee uses the "usual definition of risk aversion" (p. 815) saying that all accepted gambles with payoff w_i in state i have the property $\Sigma\pi_i w_i > 0$. But this definition stems from the case where there is a unique preference function. If there are several, as is the case here, individual behavior must be analyzed in utility space, not in money space; in other words, the marginal utility of income in each state plays a role in determining behavior.

Let us restate the argument briefly as follows: In contrast to the case where only (Y^i, P), $Y^i = Y + w_i$, differ among states we now have different $u^i(Y^i, P)$ among states. Hence, we have a utility function $U[u^i(Y^i, P)]$ instead of $U(Y^i, P)$ and expected utility as $\Sigma\pi_i U[u^i(Y^i, P)]$ instead of $\Sigma\pi_i U(Y^i, P)$. While risk aversion in the latter case is defined by $\Sigma\pi_i w_i > 0$, the relevant definition would now seem to be that $\Sigma\pi_i w_i u^i_y > 0$. If so, risk aversion is present in both cases if U is strictly concave. If, moreover, u^i is concave (which is natural to assume given the assumption of risk aversion) we have that $U^i(Y^i, P) = U[u^i(Y^i, P)]$ is strictly concave. Hence it follows from an assumption of risk aversion that U^i is strictly concave. Likewise, we may add, risk neutrality is given by U and the u^i being linear, which implies that the U^i are linear.

Given now that u^i_y and hence, that $U^i_y = U' u^i_y$ typically differ among states we can establish the following results:

(a) *Risk neutrality:*

$$OP = SC^w_{OP} \neq \Sigma\pi_i SC_i$$

If the U^i are linear functions, the right-hand sides of (6) and (7) will be the same and equal to OP. Thus, (6) or (7)—at equality—determines the option price in the absence of risk aversion. Note, however, that OP is not equal to the "expected consumer's surplus" $(\Sigma\pi_i SC_i)$ under risk neutrality. Of course, the U^i_y have no relevance for the future consumer's surpluses, the SC_i, as this is the maximum price the consumer would be

Option Demand and Consumer's Surplus: Comment

By PETER BOHM*

The concept of option values—briefly, the idea that consumers under uncertainty would be willing to pay more than the expected consumers' surplus for the option to buy a certain commodity in a future period—has for some time been a source of disagreement. Some economists have argued that option values are like the Emperor's new clothes—there just are no such things. Others argue that option values may exist and if so, that they are positive. Again, others argue that option values may equally well be negative.

An attempt to clarify this issue was recently made in an article by Richard Schmalensee. Although his contribution sheds light on important aspects of the option value problem, the relevance, and hence, the practical conclusions of his approach can be questioned. The implications of Schmalensee's results are summarized in his concluding two sentences, where he suggests that "... when tastes are the main source of uncertainty, the expected value of consumers' surpluses ought to be employed as the best available approximation to the sum of their option prices.... Benefits will sometimes be underestimated and sometimes overestimated with this procedure, but there would appear to be no practical way to obtain superior estimates" (p. 823). We shall argue that this piece of advice to investing government agencies is unacceptable. Our conclusions are presented in Section III. To begin with, we present a brief summary of Schmalensee's analysis.

I

Schmalensee intends to show that it is not generally true as argued by Charles Cicchetti and A. Myrick Freeman and others that risk aversion in the presence of uncertain future demand for a good leads to positive option values. He argues instead that option values may be positive or negative according to the specific nature of risk aversion.

The background may be described as follows. Given any investment project of the decreasing-cost type, we know that optimal prices will (may) not cover costs. In order to arrive at an investment decision we need to know how much consumers are willing to pay for (future) access to the project commodity. A concrete example may be a new line of public transportation that can be introduced next year (with fares on a given level). This can be regarded as a comparison between two sets of prices P and P^*, the latter differing from the former only to the extent that introduction of the project is equivalent to a "price reduction" of the project commodity. According to Schmalensee, the individual consumer is uncertain about his future preferences in the sense that he does not know which of a given set of alternative preference functions (future states) will hold, but he can attach given probabilities, π_i, to each state i. (As the possibility of future incomes being different in different states is irrelevant in the present context, we regard income as given.)

The consumer's surplus (SC_i) in each future state (alternative future preference function) is defined here as the compensated variation,

$$(1)\quad U^i(Y - SC_i, P^*) = U^i(Y, P)$$

The maximum willingness to pay (WTP) now, i.e., the option price (OP), is defined by

$$(2)\quad \Sigma\pi_i U^i(Y - OP, P^*) = \Sigma\pi_i U^i(Y, P)$$

Inserting (1) in (2), we get

$$(3)\quad \Sigma\pi_i U^i(Y - OP, P^*) = \Sigma\pi_i U^i(Y - SC_i, P^*)$$

Equation (3) can be rewritten in the following form:

---

rights should get all of the gains from trade, not just part.

III. Greenwood, Ingene, and Horsfield's Comment

The comment by Peter Greenwood, Charles Ingene, and James Horsfield (hereafter G-I-H) is in many ways similar to the G-S comment and to a degree suffers from similar specification problems. Like the G-S comment, G-I-H are specifying the bribes and payments in terms of changes in profit levels. Unlike G-S, the G-I-H comment attempts to deal explicitly with the bargaining situation. As with G-S, the bargaining is costless. G-I-H models develop supply and demand functions, the interaction of which is used as the determinant of the bargaining process. There are two interesting problems with this "solution." First, you have two firms in a bilateral bargaining situation where each firm is acting as a price taker. It would seem that either you have bilateral monopoly or you have firms acting as price takers, but not both simultaneously. Secondly, like the G-S paper, in the bribe and liability situations there seems to be a compromising of the property rights. The firm with the property rights has *all* the bargaining power, while the other ends up purchasing concessions. While there are of course conditions under which the property right can be "divided" and traded, the essential point (in the G-I-H comment) of *how* such division and transactions occur is based upon the inconsistency pointed out above.

IV. A Concluding Note

Our analysis was begun with the objective of looking at the Coase theorem in a specific, consistent neoclassical framework. G-S and G-I-H, in reaching conclusions contrary to ours, have also attempted to make use of a neoclassical framework. Their models, while interesting, are based on specifications and behavioral postulates which are either logically and internally inconsistent or not fully and properly developed. This latter criticism applies also to the Coelho paper. Thus, while we stand by the results contained in our original article, we anticipate continued research on the problems of externalities and the development of more fully specified and consistent bargaining models.

graphical analysis to attempt to show that the allocation of resources is invariant to the form of the cost function. Unfortunately, Coelho's analysis is deficient in a number of respects, and while the analysis that he does present seems to support his conclusion, in fact, a corrected presentation would generate our original conclusions. Referring to Coelho's graphical models, we will indicate how Coelho's analysis is faulty.

Using Figure 1, showing the total revenue and total cost curves facing firm *A*, and Figure 3, showing the total revenue and total cost curves for firm *B*, Coelho derives a locus showing the profit possibilities (in Figure 4) of the two firms if merged. This analysis is correct in showing the potential profit tradeoffs between the two processes which are possible under joint ownership. However, as drawn, Coelho's graphs do not deal with the bargaining situations and leave unclear the entire adjustment process by which equilibrium at point *N* in Figure 4 is attained if the firms are not merged. In essence, Coelho is asserting his conclusions, not proving them. In a complete analysis, Figure 1 should indicate not only the revenue based on price times quantity for firm *A*, but also the potential revenue to be gained from extracting a bribe from firm *B*. Similarly, the curves for *B* in Figure 3 should indicate the effects of money transfers between firm *A* and firm *B*, as a function of the alternative output levels. Furthermore, and this is the crucial point, the relevant total revenue and total cost curves for *both A* and *B* will depend on whether the cost function is separable or nonseparable. Coelho is correct in showing (in Figure 2) that constant parametric shifts in the total cost curve leave unchanged the profit maximizing output of the firm whose total cost curve has shifted. However, whether the shift is constant for each level of output or varies with the output depends on the separability properties and can be seen only by looking at the marginal revenue and marginal cost curves (or alternatively, the first-order conditions). This difference is at the heart of our original analysis, and the interested reader can reconstruct Coelho's curves to take into account the effects of bribes and payments on the cost functions *and* the revenue functions in the separable and nonseparable cases.

II. Gifford and Stone's Comment

In contrast to Coelho, Adam Gifford and Courtenay Stone (hereafter G-S) have presented models which are alternatives to ours and allow concrete analysis and proof. Their models specify the bribes and damage payments in terms of foregone profits rather than imposed costs as in our models. In addition their models implicitly assume that the two parties bargain costlessly and that the actual payment exchanged is some convex combination of the maximum payment the payer will give up and the minimum payment the recipient will accept. Our objections are with this aspect of their specification. The two firms being modeled are cast in a situation of bilateral monopoly. One can simply not assume some resolution in a costless manner. A costless resolution of differences or splitting of the gains from trade goes against the entire existing theory of bilateral monopoly and simply buries the eminent question in bilateral monopoly of bargaining and the gains versus the costs.

Our second objection with the G-S analysis rests with the disposition of the gains from trade. As Coelho has stressed, there are gains from trade to be had from cooperation in a situation of external diseconomies between two firms. In the two situations under contention, one or the other of the parties has the property rights assigned to them, either explicitly as when the damager is made liable or implicitly when there is no rule otherwise. For both of these situations the G-S analysis results in a splitting of the gains from trade between the two parties. It would seem that this flies in the face of the property rights assignment. The party who has the property rights is in a position to capture all of the gains from trade simply by virtue of the initial placement of the property rights. The party that does not have the property rights has no bargaining power, i.e., he is initially indifferent between paying a bribe and bearing the externally imposed cost. Thus the party with the property

Externalities, Liability, Separability, and Resource Allocation: Reply

By JAMES R. MARCHAND AND KEITH P. RUSSELL*

Ronald Coase's paper, "The Problem of Social Cost" has become a classic article in the literature on externalities. Out of that paper has come the "Coase Theorem." Coase himself never stated a theorem as such in his original paper, but subsequent papers, texts, and discussions have developed statements of Coase's main ideas in terms of a theorem. (Coase himself may not have preferred .this; perhaps proposition is better than theorem.) Statements of the Coase Theorem or proposition vary slightly from source to source, but almost all cover the same concepts. Generally most economists, the authors and their critics included, could come to some agreement on a statement of a "loose Coase Theorem." This theorem would more than likely be inclusive of the following ideas about a two-firm diseconomy situation:

1) There are possible gains from trade.
2) If the firms can merge, overall profits to the merged firm will be larger than the sum of the profits of the two separate firms.
3) If the two firms can successfully costlessly bargain, transact, or exchange, Pareto optimal output is likely to attain.

However, though economists might agree on a general Coase Theorem since Coase's paper appeared, there have been many papers attempting to examine Coase's ideas in terms of specifics and neoclassical analysis.[1] These papers have dealt with the question of how the two parties bargain, exchange, or transact given various definitions of property rights or liability and scope for negotiation. Our original paper and the comments made upon it are a part of this continuing discourse. With this frame of reference, the remainder of our reply will speak to the comments in response to our original analysis, first in general, and then in terms of the specifics of each paper.

In general one can summarize the thrust of our critics' charges with the term "model misspecification." Each of the three comments makes the claim that certain of the M-R models are misspecified. In organizational terms each of the comments is very similar in structure. Each of the three papers present alternative models which the authors contend are properly specified. On the basis of these models each of the comments either asserts or derives conclusions which are opposite to ours and sustaining of the Coase Theorem. None of the authors finds fault with our mathematical analysis. Our critics' theme seems to be that models are misspecified when they do not yield the right conclusions.

Our main response to our critics is the same as their critique of us We feel that their models are misspecified. Like our critics, we feel that their modeling and analysis is correct mathematically speaking. Where we feel that the misspecification occurs is in terms of the assumptions that our critics make. Generally speaking, it appears that our critics are making assumptions which are not in the spirit of the original situation envisioned by Coase or are making assumptions which are internally contradictory. The rest of this reply is devoted to a discussion of how these general comments apply specifically to each comment.

I. Coelho's Comment

In his comment, Philip Coelho uses a

* Assistant professors of economics, California State University, Northridge. We are indebted to Jack Hirshleifer for helpful comments. Responsibility for errors remains with us.

[1] Early papers were by G. Calabresi, F. T. Dolbear, G. W. Nutter, and R. Turvey. More recent papers are by W. Baumol, T. Crocker, G. Daly, R. d'Arge, and H. H. Liebhafsky.

may be a direct function of B's output, thereby giving A cause to bribe B to reduce its output. A will so demand until the marginal cost of its bribe equals the marginal reduction in legal payments.

Deriving A's demand for reduction of q_2, where P_3 is the price per unit reduction paid by A and q_2^1 is B's output in M-R's case C, corresponds with solving the following problem:

$$\begin{aligned}\underset{q_1;q_2}{\text{maximize}}\ \pi_1 = P_1q_1 - A(q_1)& \\ - \left[B(q_1, q_2) - B(0, q_2)\right]& \\ - P_3(\overset{1}{q_2} - q_2)&\end{aligned}$$

subject to $q_1 \geq 0$; $q_2 \geq 0$; P_3

A's demand schedule is characterized by the following conditions:

$$P_1 = A_1(q_1) + B_1(q_1, q_2) \tag{6}$$

$$P_3 = B_2(q_1, q_2) - B_2(0, q_2) \tag{7}$$

Since when costs are separable $B_2(q_1, q_2) \equiv B_2(0, q_2)$, A has no demand for bribing B; no bribing occurs. The allocation resulting is given by M-R (equations (5′) and (6′)), and again this is the optimal allocation.

In either case, B is willing to supply reduction to the point where the marginal bribe received equals the marginal pre-bribery profit foregone. B's "supply" of reduction is found as the result of the following problem:

$$\begin{aligned}\underset{q_2}{\text{maximize}}\ \pi_2 = P_2q_2 - B(0, q_2)& \\ + P_3(\overset{1}{q_2} - q_2)&\end{aligned}$$

subject to $q_2 \geq 0$; P_3

B's "supply" is given by:

$$P_3 = P_2 - B_2(0, q_2) \tag{8}$$

Combining (6), (7), and (8) yields the optimal allocation. Thus, it has been shown that the allocation of resources is independent of both the legal framework and the nature of the cost functions when transactions are costless, and both are price takers.

Throughout this comment we have made a pair of assumptions, one explicit, the other implicit. The latter has been that all bribery results are marginal, that is, neither firm will discontinue operations as the result of bribery payments or legal sanctions. The former assumption has been that both firms act as price takers in the bribery market. If such a situation does not hold, if one or both of them attempt to exert market power, the optimal allocation of resources is in general destroyed.

We analyze one case of market power, leaving other cases to the interested reader. The legal system permits A to impose uncompensated external costs upon B, and A is aware of B's demand function. A's decision is summarized by:

$$\begin{aligned}\underset{q_1;q_2}{\text{maximize}}\ \pi_1 = P_1q_1 - A(q_1)& \\ + B_1(q_1, q_2)(\hat{q}_1 - q_1)& \\ + \lambda\left[P_2 - B_2(q_1, q_2)\right]&\end{aligned}$$

subject to $q_1 \geq 0$; $q_2 \geq 0$

The solution of this problem is the allocation of resources which is characterized by the following conditions:

$$P_1 = A_1 + B_1 - (\hat{q}_1 - q_1)(B_{11}B_{22} - B_{12}^2)/B_{22} \tag{9}$$

$$P_2 = B_2 \tag{10}$$

These conditions imply the optimal allocation only when the last term of (9) is zero. The optimal allocation clearly cannot be guaranteed.

However, this does not mean that the optimal allocation cannot be reached. As long as further gains can be made there is incentive for (costless) negotiations to continue, and there are always gains to be shared when the allocation is suboptimal.

We hope this comment on the topic of externalities will aid in the understanding of Coase's basic argument about the nature of markets.

Externalities, Liability, Separability, and Resource Allocation: Comment

By Peter Greenwood, Charles Ingene, and James Horsfield*

In a recent article in this *Review*, James Marchand and Keith Russell (M-R) attempt to demonstrate that " . . . the neutrality of liability on resource allocation holds only in the restricted case of additively separable cost functions" (p. 611). M-R reach this conclusion because they incorrectly specify the form that a bribe between two firms—the injurer (A) and the injured (B)—will take. When the bribery market is correctly specified, the form of the cost functions has no effect on the allocation of resources; further, the allocation of resources does not depend upon the delimitation of liability by the legal system. In this comment we establish a neoclassical market framework within which we analyze the various situations described by M-R; this analysis supports what they term "a 'generalized' Coase theorem" (p. 618).

The nature of the trades is dependent on the legal framework. Specifically, assume that the legal system permits A to impose external costs on B without requiring compensation. B has cause to bribe A in order to obtain a reduction in A's output. B will so "demand" to the point where the marginal cost of the bribe is equated with its marginal (external) cost reduction. The derivation of B's demand corresponds with the solution of the following problem; where P_3 is the parametric bribe paid by B per unit of reduction of q_1, $\hat{q}_1$ is A's pre-bribery output (M-R case A), and the remaining notation is given by M-R:

$$\underset{q_1;q_2}{\text{maximize}}\ \pi_2 = P_2q_2 - B(q_1, q_2) - P_3(\hat{q}_1 - q_1)$$

$$\text{subject to } q_1 \geq 0; \quad q_2 \geq 0; \quad P_3$$

B's demand schedule is implied by the following conditions:

$$(1) \qquad P_2 = B_2(q_1, q_2)$$

$$(2) \qquad P_3 = B_1(q_1, q_2)$$

Firm A will "supply" B with a reduction in quantity until the marginal bribe received is equal to the marginal pre-bribery profit foregone. An alternative but equivalent statement is that A will produce until the price it receives for its product is just equal to the sum of its marginal cost and the marginal bribe. The derivation of A's supply schedule corresponds with the following problem:

$$\underset{q_1}{\text{maximize}}\ \pi_1 = P_1q_1 - A(q_1) + P_3(\hat{q}_1 - q_1)$$

$$\text{subject to } q_1 \geq 0; \quad P_3$$

The answer to this problem yields the following supply function:

$$(3) \qquad P_3 = P_1 - A_1(q_1)$$

Provided that both A and B approach the bribery market with a competitive spirit (as price takers), A will reduce its output until B's marginal (external) cost equals A's marginal pre-bribery profit foregone. This represents an optimal allocation of resources, as can be seen by combining equations (1), (2), and (3) to obtain (M-R's equations (7) and (8)):

$$(4) \qquad P_1 = A_1(\overset{*}{q}_1) + B_1(\overset{*}{q}_1, \overset{*}{q}_2)$$

$$(5) \qquad P_2 = B_2(\overset{*}{q}_1, \overset{*}{q}_2)$$

This is the efficient allocation; the result is invariant with respect to the nature of the cost functions.

We now consider a legal system which does not permit the imposition of uncompensated external costs. A's legally required payments sis in Section II indicates. The value of Marchand and Russell's analysis is that while clearly incorrect in their specification of the inapplicability of Coase's results for the nonseparable cost situation, their results serve as a reminder that legal definitions when different from economic ones, will affect resource allocation and economic efficiency. An additional caveat from their analysis is that resource efficiency is not aided by incorrectly specifying the economic damage imposed by negative externalities.

which is, of course, firm A's reduction in profits from its decrease in output. The maximum bribe that firm B will offer firm A for such a reduction is

$$C^B = p_2q_2 - B(q_1, q_2) - p_2\hat{q}_2 + B(\hat{q}_1, \hat{q}_2)$$

which is firm B's increase in profits consequent to firm A's reduction in output and firm B's expansion to its new optimal rate, q_2. C^A and C^B represent the limits to the actual bribe, C, which can be represented as

$$C = \alpha C^A + (1 - \alpha)C^B; \qquad \alpha \in (0, 1)$$

where the level of α is determined by the bargaining strategies of the two firms.[3] From the objective functions for the two firms:

Firm A: $\underset{\{q_1\}}{\text{Maximize:}}$ $p_1q_1 - A(q_1) + C$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize:}}$ $p_2q_2 - B(q_1, q_2) - C$

subject to $q_2 \geq 0$

come the following solutions:

$$p_1 = A_1(\overset{*}{q}_1) + B_1(\overset{*}{q}_1, \overset{*}{q}_2) \tag{12}$$

$$p_2 = B_2(\overset{*}{q}_1, \overset{*}{q}_2) \tag{13}$$

which are identical to M-R's socially optimal solutions (7) and (8).

Environment C. If firm A is "fully liable" for the imposition of the externality, then firm B has the property right to the profit resulting from the maximization problem:

Firm B: $\underset{\{q_2\}}{\text{Maximize:}}$ $p_2q_2 - B(0, q_2)$

subject to $q_2 \geq 0$

which yields firm B's maximum profit when

$$p_2 = B_2(0, \bar{q}_2) \tag{14}$$

where $\bar{q}_2$ is firm B's optimal output rate *in the absence of the externality*. Since firm B must be guaranteed at least this profit level, the minimum payment that firm B will require firm A to pay in order to produce some positive output level q_1 is

$$L^B = p_2\bar{q}_2 - B(0, \bar{q}_2) - p_2q_2 + B(q_1, q_2)$$

where, again, q_2 is firm B's optimal output when firm A produces q_1. The maximum liability that firm A will incur is the difference between its profits here and its next most profitable opportunity (different location or industry). As this alternative profit is an opportunity cost to firm A, it appears in firm A's cost function, making firm A's maximum bribe $L^A = p_1q_1 - A(q_1)$. The actual liability incurred[4] is

$$L = \tilde{\alpha}L^A + (1 - \tilde{\alpha})L^B; \qquad \tilde{\alpha} \in (0, 1)$$

The maximization problem for the firms is now

Firm A: $\underset{\{q_1\}}{\text{Maximize:}}$ $p_1q_1 - A(q_1) - L$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize:}}$ $p_2q_2 - B(q_1, q_2) + L$

subject to $q_2 \geq 0$

resulting in the following solutions:

$$p_1 = A_1(\overset{*}{q}_1) + B_1(\overset{*}{q}_1, \overset{*}{q}_2) \tag{15}$$

$$p_2 = B_2(\overset{*}{q}_1, \overset{*}{q}_2) \tag{16}$$

Again, the levels of output are identical with those obtained for the previous problem (12) and (13) and for M-R's social optimal output rates (7) and (8). Different *economic* liability rules do *not* result in different social resource allocation in the nonseparable cost situation.

III. Liability Definitions and Resource Use

That Coase's Theorem holds irrespective of either the property right assignment or the form of the cost function is not surprising. Profit-maximizing firms will respond to changes in their profit possibilities by adjusting the levels of output to maximize the total value of output when property rights are exchangeable at zero costs—as the analy-

---

[3] Ruling out a corner solution necessarily requires that $C^B > C^A$. The possibility of corner solutions, however, in no way affects Coase's conclusions. For a complete discussion, see the authors.

[4] Similar to the discussion in fn. 2, ruling out a corner solution requires that $L^A > L^B$.

$$+ [B(\hat{q}_1, q_2) - B(q_1, q_2)]$$

subject to $q_1 \geq 0$

Firm B: $$\underset{\{q_2\}}{\text{Maximize:}} \quad p_2q_2 - B(q_1, q_2) - [B(\hat{q}_1, q_2) - B(q_1, q_2)]$$

subject to $q_2 \geq 0$

resulting in outputs q_1'' and q_2'' from the solution values:

$$(3) \qquad p_1 = A_1(q_1'') + B_1(q_1'', q_2'')$$

$$(4) \qquad p_2 = B_2(\hat{q}_1, q_2'')$$

C. Imposition of Liability. (Firm A imposes an externality on firm B; firm B has the (property) right to have firm A compensate firm B for the damage imposed.) M-R state: "... a law or judge ... [declares] ... firm A liable for the extra costs experienced by firm B in a state of nature. Liability is therefore $L = B(q_1, q_2) - B(0, q_2)$" (p. 614). The relevant decisions for the firms are now

Firm A: $$\underset{\{q_1\}}{\text{Maximize:}} \quad p_1q_1 - A(q_1) - [B(q_1, q_2) - B(0, q_2)]$$

subject to $q_1 \geq 0$

Firm B: $$\underset{\{q_2\}}{\text{Maximize:}} \quad p_2q_2 - B(q_1, q_2) + [B(q_1, q_2) - B(0, q_2)]$$

subject to $q_2 \geq 0$

yielding the solution values

$$(5) \qquad p_1 = A_1(q_1') + B_1(q_1', q_2')$$

$$(6) \qquad p_2 = B_2(0, q_2')$$

D. Centralized Decision Making. (Firm A and firm B merge, thereby internalizing the externality.) The relevant objective function for the new super-firm is:

$$\underset{\{q_1, q_2\}}{\text{Maximize:}} \quad p_1q_1 + p_2q_2 - A(q_1) - B(q_1, q_2)$$

subject to $q_1 \geq 0$; $q_2 \geq 0$

which yields the socially optimal (for resource allocation) outputs

$$(7) \qquad p_1 = A_1(\overset{*}{q}_1) + B_1(\overset{*}{q}_1, \overset{*}{q}_2)$$

$$(8) \qquad p_2 = B_2(\overset{*}{q}_1, \overset{*}{q}_2)$$

M-R then show (for their assumptions about the second-order partial derivatives) that:

$$(9) \qquad \hat{q}_1 > \overset{*}{q}_1 \quad \text{and} \quad \hat{q}_2 < \overset{*}{q}_2$$

$$(10) \qquad q_1' < \overset{*}{q}_1 \quad \text{and} \quad q_2' > \overset{*}{q}_2$$

$$(11) \qquad q_1'' > \overset{*}{q}_1 \quad \text{and} \quad q_2'' < \overset{*}{q}_2$$

M-R conclude that "In the more complicated, yet more realistic world where production externalities involve nonseparable cost functions, the allocation of resources is not independent of the legal framework. As the inequalities (9)–(11) show, the allocation of resources depends on the definition of liability" (p. 618).

We now demonstrate that while the allocation of resources does indeed depend upon the *legal* definition of liability, Coase's Theorem applies generally, regardless of the nature of the cost function.

II. The Generalized Coase Theorem[2]

The Coase Theorem, as derived from an economic analysis of the impact of different property-right (liability) assignments on resource allocation, is clearly based on an *economic* definition of liability. Given the competitive situation under analysis, achieving the greatest value of production involves using resources in their highest-valued (i.e., most profitable) use. Therefore, the economic cost (damage) that firm A inflicts on firm B is the decrease in firm B's *profits* consequent to the external effect generated by firm A. It is easy to show that by using foregone profits as the cost or damage for liability purposes, Coase's Theorem holds regardless of the form of the cost function. Reconsider M-R's environments B and C, using the economic definition of liability.

Environment B. If firm A is assigned the right to generate the externality, it will reduce its output (and also the external effect) from $\hat{q}_1$ to q_1 for any bribe larger than

$$C^A = p_1\hat{q}_1 - A(\hat{q}_1) - p_1q_1 + A(q_1)$$

---

[2] This analysis is based on an extended presentation developed elsewhere by the authors.

Externalities, Liability, Separability, and Resource Allocation: Comment

By ADAM GIFFORD, JR. AND COURTENAY C. STONE[*]

In a recent article in this *Review*, James Marchand and Keith Russell deny the generality of Ronald Coase's classic analysis of the two-firm externality situation where transactions cost and income-redistribution effects on demands are zero. Specifically, Marchand and Russell (M-R) state that "... Coase's conclusion regarding the neutrality of liability on resource allocation holds only in the restricted case of additively separable cost functions" (p. 611). Their analysis indicates that in the case of nonseparable cost functions, not only will the levels of output differ depending upon the allocation of liability (thereby challenging Coase's symmetry results), but also that the levels of output will differ from the socially optimal output levels regardless of the liability assignment (challenging Coase's implications for efficient resource allocation).

We show that M-R's seemingly startling conclusions result not from the form of the cost function, but from their own peculiar specifications of the opportunity cost of the externality under different property-right assignments. We first summarize the M-R analysis for the nonseparable cost function case. This is followed by the corrected analysis which demonstrates that Coase's conclusions are independent of the form of the cost function. Finally, some aspects of the importance of different definitions of liability and property rights are examined.

I. M-R's Analysis

Marchand and Russell state:

> Consider two firms, A and B, each a member of a different competitive industry, whose productive processes interact. Denote A and B outputs as q_1 and q_2 and their total cost functions as $A(q_1)$ and $B(q_1, q_2)$, respectively. (These functions relate the costs of the inputs purchased directly by the firms to the levels of output indicated in the arguments.) Assume that $A_1>0$, $B_1>0$, $B_2>0$, $A(0)=0$, and $B(q_1, 0)=0$. [p. 612]

From this initial situation M-R develop four alternative scenarios, or "environments."

A. Simple Profit Maximization. (Firm A imposes an externality on firm B; firm B can't find firm A.) From the objective functions for the two firms:

Firm A: $\underset{\{q_1\}}{\text{Maximize:}}\quad p_1q_1 - A(q_1)$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize:}}\quad p_2q_2 - B(q_1, q_2)$

subject to $q_2 \geq 0$

the resulting first-order conditions for a maximum involve the solutions:[1]

$$(1)\qquad p_1 = A_1(\hat{q}_1)$$

$$(2)\qquad p_2 = B_2(\hat{q}_1, \hat{q}_2)$$

B. Expanded View of Profit Maximization. (Firm A imposes an externality on firm B and has the (property) right to do so; firm B offers a bribe (compensation) to firm A to reduce the externality.) M-R state: "... the compensation which B would be willing to pay ... is equal to the cost saving B receives as a result of A's producing less than $\hat{q}_1$; that is, compensation would be $C=(B(\hat{q}_1, q_2) - B(q_1, q_2))$" (p. 613). From the relevant objective functions (including the compensation):

Firm A: $\underset{\{q_1\}}{\text{Maximize:}}\quad p_1q_1 - A(q_1)$

---

[1] The following equations and numbering up to and including equation (11) correspond to the M-R equations and numbering.

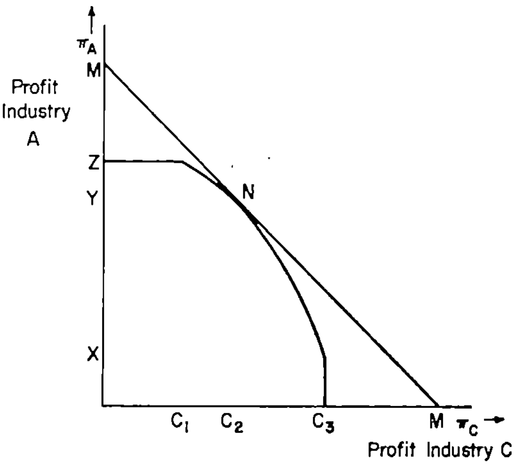

FIGURE 4

in keeping with the basic assumption behind the Coase Theorem—that negotiations between the two parties are feasible. Figure 4 illustrates the point. The curve ZNC_3 is the locus of points which show the maximum profit available to industry C for given levels of profit in industry A. This curve will be called the profit-opportunity locus. The line $(M-M)$ tangent to the profit-opportunity locus at N is the highest indifference curve the entrepreneur and society can reach. The indifference curve MM is a straight line with a slope of -1, indicating that neither society nor the entrepreneurs care from which industry the dollars of profit come. As long as point N is not reached, both parties can be made better off (i.e., each can have a little more profit) by negotiating (trading) until point N is reached.

The mathematics that Marchand and Russell present are flawless. Their economic logic leaves something to be desired. In Section IB, "An Expanded View of Profit Maximization" (p. 613), the entrepreneurs are presumed ignorant of the true nature of their joint production functions. What else can explain the failure of one of the businessmen to offer to buy out the other (for a dollar more than the capitalized value of his firm) and then proceed to maximize joint profits? As I have pointed out, merger is not the only solution; with reference to Figure 4 a system of side payments *can and will be made* assuming no transaction costs and knowledge of the profit-opportunity locus. If one party lacks the knowledge of the profit-opportunity locus and the other has it, then an outright purchase of the ignorant industry will be made by the knowledgeable industry. Only if both parties are ignorant will the Marchand and Russell conclusions hold.

The line of reasoning pursued here is not dependent upon the shape of the profit-opportunity locus. Any frontier of whatever shape will do equally well. It is dependent upon the shape of the indifference curve. Our optimum point N will only be reached if the indifference curve for profits is a straight line with a slope of -1. In essence, the Coase Theorem holds no matter what the nature of the cost function is, given 1) an absence of ignorance by at least one of the parties and 2) no transaction costs. It seems likely that if the respective industries are unaware of the nature of the externalities then all other parties would be equally ignorant. In this final case the question of optimum subsidies or taxes becomes moot.

Obviously, in the real world there are transaction costs, and knowledge does cost resources. Whether we should rely upon voluntary or governmental action in a specific case depends upon the equally obvious point: the difference between private and governmental costs of acquiring knowledge and of enacting transactions.

the additional costs were added to industry *B*.

Figure 3 depicts an industry (*C*) that has a nonseparable cost function. (In order to simplify the following discussion, no reference will be made to Figure 2 nor to industry *B*; we will deal with solely two industries, *A* and *C*. The addition of a third industry does not change our analysis, it adds a third dimension, however.) Industry *C*'s total cost function depends upon the level of output it produces and the level of output in industry *A*. The output of industry *A* enters multiplicatively in the cost function of *C*; i.e., the cost function is nonseparable.

This is demonstrated by observing that the profit-maximizing output of industry *C* changes as output in *A* changes. If industry *A*'s output is *Z* (the output that would maximize industry *A*'s profits in the absence of side payments to or from *C*), then the profit function for *C* will be $\pi(Z)$ and the profit-maximizing output will be C_1 in industry *C*. If industry *A*'s output is at *X* (the maximum output industry *A* can produce without generating externalities), industry *C* will produce output C_3 and achieve its maximum profit on the profit function $\pi(X)$.

Suppose that outputs *Y* of industry *A* and C_2 of the *C* industry are the outputs that maximize joint industry profits. Marchand and Russell argue that if industry *C* is forced to pay a bribe to prevent some damage, industry *C* will produce less than the joint profit-maximizing solution and industry *A* will produce more. In the case where liability for damage rests upon industry *A* their results are reversed. However, their argument explicitly constrains the entrepreneurs to these outcomes.[3] This is neither realistic nor

---

[3] They state: "Finally, *it is possible* that one might argue against our results on the grounds that we did not allow the individuals concerned sufficient scope to negotiate. That is, no matter what liability rule is in effect any arrangements are preliminary in nature and lead to more complex negotiation such that it is possible for individuals to merge and attain the jointly optimal solution" (pp. 617–18, emphasis added). This is precisely the point of Coase's article! Yet, their mathematics constrain the entrepreneurs to a nonoptimal point. The situation is analogous to Cournot's solution to the duopoly problem: the mathematics are impeccable, the economic logic motivating the individuals described by the math is ludicrous.

Externalities, Liability, Separability, and Resource Allocation: Comment

By PHILIP R. P. COELHO*

In a recent article in this *Review*, James Marchand and Keith Russell have disputed the generality of the Coase Theorem. The essence of this theorem is that in the absence of negotiation and transaction costs, an externality will have no effect upon the efficient allocation of resources regardless of where the liability for damage rests.

The argument of Marchand and Russell stresses the difference between separable and nonseparable cost functions. The Coase Theorem is shown by the authors to be true for separable cost functions but not for nonseparable functions.[1] I see no merit in the distinction. This note will show that given the Coase assumptions, the Coase Theorem is valid no matter what the nature of the cost function. In the following, a heuristic approach to the problem will be employed. It is my opinion that the strict mathematics is what led the authors into incorrect economic analysis.

A separable cost function is distinguished from a nonseparable one in that it can be divided into additive terms with only one variable per term. Consequently, when a separable cost function is differentiated with respect to its (own) output, marginal cost is solely a function of output. A nonseparable cost function cannot be segregated into additive terms with only one variable per term. Consequently, the marginal cost function of a nonseparable cost function will have other variables in it besides its (own) output.

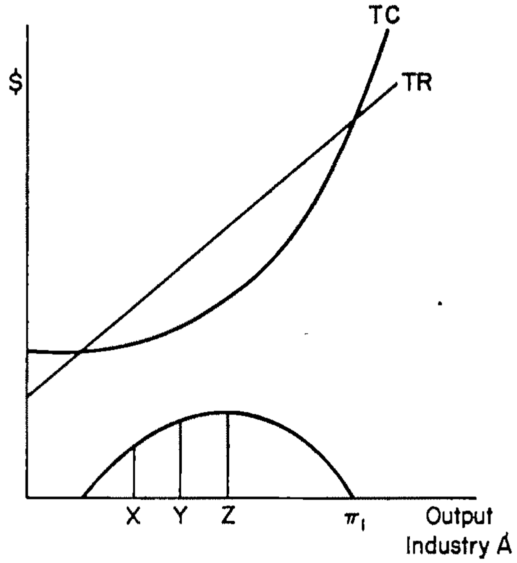

FIGURE 1

The following figures illustrate the distinction. Figure 1 depicts industry A which is an industry that is not subject to externalities and consequently has a separable cost function. TR and TC are abbreviations for total revenue and total cost, π is the total profit function. Figure 2 depicts an industry that has a separable cost function and that is subject to externalities.[2] As the output of industry A increases, costs in industry B increase. However, the profit-maximizing output does not change in industry B; the only change that occurs is that the cost curves shift up by a constant for each increase in cost imposed by the output of industry A. Figures 1 and 2 will be recognized as the "normal" total cost, total revenue, and total profit curves found in microeconomics texts. Figure 2 differs from Figure 1 by varying constants added to the total cost curve. Consequently, the marginal conditions for profit-maximizing output will not differ from what they were before at level $1/2\ P_m$ where P_m is the highest willingness-to-pay for any demanded consumption unit. The marginal cost curve intersects the marginal benefit curve at points associated with capacities Q_1 and Q_m. But capacity Q_1 minimizes net benefits because the marginal cost curve intersects the marginal benefit curve from above. Therefore, the correct intersection is the one associated with capacity Q_m since here the marginal cost curve intersects the marginal benefit curve from below. However, the area under the marginal cost curve from 0 to Q_m is just equal, by construction, to the area under the marginal benefit curve from 0 to Q_m, so at capacity Q_m net benefits are zero. This means we should just be indifferent between a capacity of zero or a capacity of Q_m. On the other hand, for any marginal cost curve that is constant at a level that is less than $1/2\ P_m$, the area under the marginal cost curve will be less than that enclosed by the marginal benefit curve, so net benefits are greater than zero, and the optimum capacity is Q_m. Similarly, for any marginal cost curve that is constant at a level that is higher than $1/2\ P_m$ the optimum capacity is zero.

---

* Washington State University.

[1] Separability and nonseparability are discussed in Marchand and Russell, and Otto Davis and Andrew Whinston.

[2] In the following, industry A will be the externality-imposing industry. Obviously, it makes no difference which industry imposes the externality; less obviously, it does not matter if each industry imposes an externality because there will be one dominant profit-opportunity locus at each relevant point.

V. Conclusions

Theoretical as well as practical developments in benefit-cost analysis have assumed that marginal cost pricing will be used in conjunction with standard evaluative and investment criteria. However, political and institutional realities often tend to support policies in which public products are priced below marginal cost. In this paper, we have developed evaluative and investment criteria appropriate for the cases in which public products are underpriced (for example, zero priced). Utilization of the new criteria that assume underpricing leads to an increase in efficiency in these situations. Our results are based upon the assumption that consumers will be drawn from a random sample of all consumers who would like to obtain the output at the set price. Even though this assumption is probably the most reasonable and was used in our calculations, others could also have been made. Several alternatives were reviewed to illustrate how they might be incorporated into our analysis. Although we have ignored possible equity benefits that might be obtained by deviating from marginal cost pricing, our analysis does establish the proper measure of efficiency benefits against which equity benefits can be compared in cases of zero or underpricing.

Our analysis suggests that benefit-cost analysis cannot be conducted independently of the pricing policy chosen to allocate an undertaking's capacity. Either prices must be set equal to marginal cost and the standard evaluative criteria used, or if prices are set below marginal cost, then alternate evaluative criteria must be used.

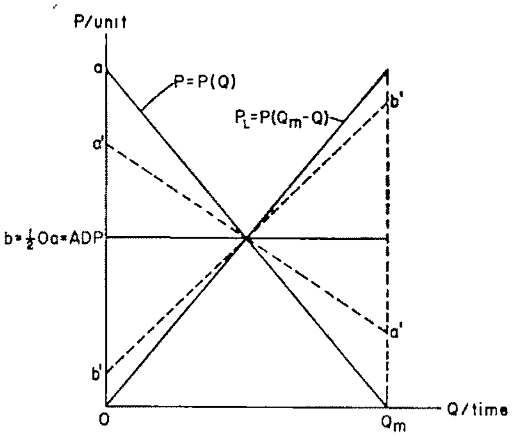
Figure 3. The marginal benefit is given by the demand-price of the last unit satisfied and is $P_L=P(Q_m-Q_1)$. Since $P(Q)$ is a decreasing function with respect to Q, $P(Q_m-Q)$ is an increasing function with respect to Q (see Figure 4). The three marginal benefit functions associated with the assumptions mentioned in this section are summarized for the case of a linear demand function in Figure 4.

Variations of the above assumptions can also be incorporated into our analysis. In the case where higher willingness-to-pay units have a greater probability (but not equal to one) of being satisfied before lower willingness-to-pay units, the slope of the expected marginal benefit curve will be somewhere between that of $P(Q)$ and ADP, for example, curve $a'a'$ in Figure 4. Alternatively, if lower willingness-to-pay units have a greater probability of being satisfied than higher willingness-to-pay units, the expected marginal benefit curve will have a slope somewhere between that of $P(Q_m-Q)$ and ADP, for example, curve $b'b'$ in Figure 4.

To determine optimum capacity in these cases, one would find the point where the marginal cost curve intersects the appropriate marginal benefit curve from below, and then determine whether or not total benefits are greater than total costs at this point. If total benefits are greater than total costs then this intersection determines the optimum capacity, but if total benefits are less than total costs then the optimum capacity is zero. However, note that all of the marginal benefit curves, except for the demand price curve, have discontinuities at Q_m. These discontinuities must be treated as vertical segments of the marginal benefit curves so that the marginal cost curve passing through the discontinuity represents an intersection of the marginal benefit function from below. This feature of the marginal benefit functions increases the importance of second-order and total conditions in determining the optimum capacity, and gives rise to many situations where the optimum capacity is either zero or Q_m. This is illustrated in Figure 5.



$P=P(Q)$ = highest willingness-to-pay units satisfied first

ADP = each unit has an equal probability of being satisfied

$P_L=P(Q_m-Q)$ = lowest willingness-to-pay units satisfied first

FIGURE 4. MARGINAL BENEFIT FUNCTIONS FOR DIFFERENT RATIONING ASSUMPTIONS

Figure 5 represents a case where the lowest willingness-to-pay units are satisfied first, so the marginal benefit curve is given by the curve labelled P_L. Marginal cost is constant

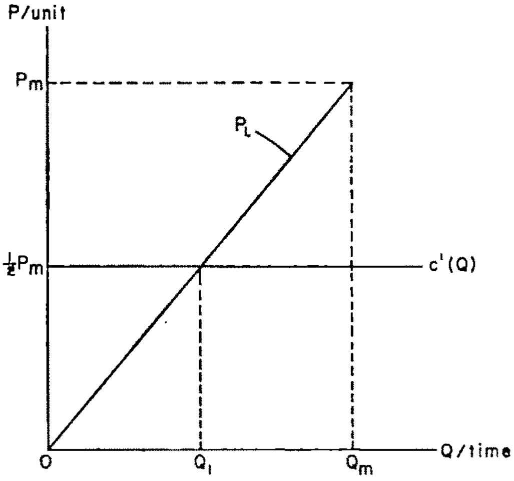


FIGURE 5. CAPACITY DETERMINATION WITH LOWEST WILLINGNESS-TO-PAY UNITS SATISFIED FIRST AND CONSTANT MARGINAL COST

an exclusion cost (*EC*) all nonpayers could be excluded from a project's benefits. If one uses the standard investment criterion for choosing capacity, the incurring of exclusion costs may erroneously appear to be worthwhile in many cases. For example, in Figure 1 capacity Q^* maximizes net benefits when Q goes unpriced, so at zero price Q^* offers greater net benefits than capacity $\hat{Q}$. Therefore, for some values of *EC*, the potential gain in net benefits from excluding nonpayers at capacity $\hat{Q}$ (equal to the difference between area *acd* and area *bcde*) will exceed *EC*. However, if an increase in capacity to Q^* is considered, the potential gain from exclusion (equal to the difference between area *acd* and area *bcf*) will be less than *EC*. Now if we calculate zero pricing benefits at capacity Q^* the pricing policy criterion is as follows: If the gain from exclusion exceeds *EC*, charge marginal cost and choose capacity $\hat{Q}$ (from standard investment criterion); if the gain from exclusion is less than *EC*, price at zero and choose capacity Q^* (from the new zero-pricing investment criterion).

IV. Alternative Nonprice Rationing Assumptions

When effective demand exceeds capacity, it becomes necessary to make some sort of assumption regarding the mechanism used to determine which consumers will be successful in acquiring the output. We believe that the most reasonable assumption, and the assumption employed in our analysis, is one in which each of the demanded consumption units at a given price has an equal probability of being satisfied. Other rationing assumptions, however, are possible. To illustrate how different assumptions would alter our results, we briefly analyze and compare the marginal benefit function for the zero price case under two alternative rationing assumptions: 1) the highest willingness-to-pay consumption units demanded are satisfied first; and 2) the lowest willingness-to-pay units demanded are satisfied first.

In some situations, the first rationing assumption might be the most reasonable. For example, if reservations are used to allocate capacity, it might be reasonable to suppose that the consumers who would be willing to pay the most would be the ones who obtained reservations first or if a lottery in which all consumers had an equal chance of obtaining a reservation were instituted, a perfect speculators market in reservations might develop and the reservations of low-valued consumers would be transferred to high-valued consumers. If queuing and transactions costs were absent in these situations, the result would be the same as if a price were charged to allocate output to its highest willingness-to-pay users. In this case, the marginal benefit function is given by the standard demand-price function $P=P(Q)$, rather than the average demand-price function.

It is also possible to posit situations in which the lowest willingness-to-pay units are satisfied first. Let us assume that the low willingness-to-pay users obtain reservations well in advance of actual consumption and that the high willingness-to-pay users attempt to make reservations on short notice. If no transfers are allowed or if transfer costs are too high, the lowest willingness-to-pay units will obtain reservations first. In this case, the consumption units that are satisfied by any output Q_1 are those from (Q_m-Q_1) to Q_m on the demand-price function. The total gross benefits for output Q_1 are given by the area under the demand-price function $[P=P(Q)]$, from (Q_m-Q_1) to Q_m as shown in

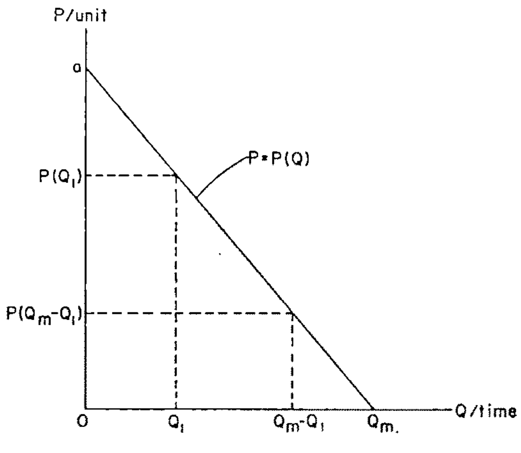

FIGURE 3. VALUATION OF BENEFITS FOR LOW VALUED USERS

This case is analogous to the zero price case. The only difference is that, in the underpricing case, the average demand price is the average over the quantities from zero to $\bar{Q}$, instead of zero to Q_m.

If $\bar{P}=0$, then $\bar{Q}=Q_m$ and equation (6) is identical to equation (4). Now suppose we impose the marginal cost-pricing rule, i.e., $\bar{P}=P(\bar{Q})=C'(\bar{Q})$. This implies that $Q(\bar{P})=\bar{Q}$, which means that Q and $\bar{Q}$, in the first term of equation (6), cancel out and the upper limit of the definite integral becomes $\bar{Q}$. Thus, equation (6) becomes a specific example of the generalized equation (1), and marginal cost pricing and zero pricing are special cases of underpricing. It could be shown, in a manner analogous to that used in the first section of the paper, that welfare losses from using an investment criterion derivable from equation (6) will generally be less than welfare losses resulting from using (2), if a price less than marginal cost is charged.

III. Implications of the Analysis for Project Scale and the Imposition of User Fees

Now that evaluation criteria have been developed, we examine whether the new criteria will yield capacities that are greater than, less than, or equal to those determined by the standard criterion when public products are underpriced. Without information concerning the cost and demand functions, it is impossible to say a priori whether capacity determined by the new criterion is greater than, equal to, or less than capacity determined by the standard criterion. However, if no prices are charged, if increasing costs exist, and if P represents the price indicated by the marginal cost price criterion, the relevant relationships are: if $P=P(Q)=C'(Q)\gtreqless ADP$, then $Q^*\gtreqless\hat{Q}$ where Q^* and $\hat{Q}$ are the capacities determined by the new and standard criteria, respectively. This relationship is shown graphically in Figure 2, which is the same as Figure 1, except that now we have three alternative marginal cost curves. In the case of $C_1'(Q)$, $P(Q)=C_1'(Q)>ADP$ and $Q_1^*<\hat{Q}_1$; for $C_2'(Q)$, $P(Q)=C_2'(Q)=ADP$ and $Q_2^*=\hat{Q}_2$; and for $C_3'(Q)$, $P(Q)=C_3'(Q)<ADP$ and $Q_3^*>\hat{Q}_3$.

The same capacity relationships hold for conditions of constant costs, except when $C'(Q)$ is everywhere equal to ADP; if the new criterion is used, capacity is indeterminate. Furthermore, we know that under conditions of constant costs the new evaluative criterion will determine capacity to be zero, if $C'(Q)$ is greater than ADP, and capacity will be Q_m, if $C(Q)'$ is less than ADP.

Under conditions of decreasing costs, if the total condition (total benefits exceed total costs) is met, the new criterion will always select capacity Q_m, which is greater than the capacity that will be selected by the standard criterion. However, there are cases in which the total condition will be met by the standard welfare measure, but not by the new welfare measure, because total benefits calculated for any given capacity are greater when using the standard measure rather than the new one except at Q_m, where both measures yield the same benefits. In these situations, the standard criterion results in a greater capacity, since there is no investment if the new criterion is used.

Another result of our analysis is a criterion for the choice of pricing policy when the exclusion of nonpayers is possible but costly. High exclusion costs are frequently used to justify the practice of not charging prices for public products. Suppose that by incurring

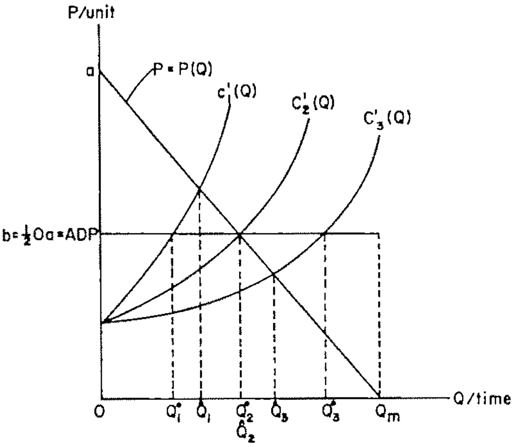

FIGURE 2. CAPACITY DETERMINATION WITH STANDARD AND NEW INVESTMENT CRITERIA ZERO-PRICING CASE

the marginal cost function intersects ADP from above instead of from below,[4] the optimum capacity is Q_m.[5] In this second case, the expected marginal gross benefit function is ADP. Therefore, expected marginal benefits exceed marginal costs until Q_m is reached. At Q_m all demand is satisfied, marginal benefits are zero and the optimum capacity is reached.

We can now see that when prices are not charged for public products, the standard investment criterion (2) and the new investment criterion (5) will not usually lead to the same choice of capacity. It would be strictly coincidental to find $P(Q)=C'(Q)=ADP$, which are the necessary conditions for the same capacity to be selected using both criteria.

The potential welfare gain from the use of equation (5) rather than equation (2) as an investment criterion can be easily illustrated. When it is assumed that price will ration capacity to its highest-valued uses, net benefit is the difference between the area beneath the demand curve and the area beneath the marginal cost curve at the level of Q chosen. Using the standard evaluative criterion of equation (2), optimum capacity in Figure 1 is $\hat{Q}$, where the demand and marginal cost curves intersect. If price $\hat{P}$ equal to marginal cost $C'(\hat{Q})$ is used to allocate $\hat{Q}$, net benefits equal the area *acd*. But if no price is charged, the expected net benefit from capacity $\hat{Q}$ is not the area *acd*. Assuming all consumption units from zero to Q_m have an equal probability of being satisfied, expected net benefit is the area beneath the average demand price curve (here a constant (1/2) Oa since demand is drawn as a linear function) minus the area beneath the marginal cost curve at the level of Q chosen. At capacity $\hat{Q}$, then, expected net benefit at a zero price equals the area *bcde*. Expected net benefit can be increased by using the investment criterion in equation (5) and extending capacity from $\hat{Q}$ to Q^*. At Q^*, average demand price equals marginal cost, and an offer of capacity Q^* rather than $\hat{Q}$ increases welfare by the amount *edf*.

II. The Under-pricing Case

By extending our analysis of welfare measures and investment criteria for the zero-pricing case, we develop a measure of welfare and investment criteria for the more general case of underpricing. In the underpricing case, a positive price $\bar{P}$ is levied for a given output and capacity of $\bar{Q}$, such that $\bar{P}<P(\bar{Q})$.

We assume $Q=Q(P)$ to be the demand function which is the unique inverse of our demand price function $P=P(Q)$. For the underpriced case, where $Q=Q(\bar{P})>\bar{Q}$ and thus greater than capacity, we are again interested in determining the expected value of the demanded consumption units that are satisfied. If we assume each of the $\bar{\bar{Q}}$ units has an equal probability of being satisfied, the expected value (ADP) of a satisfied unit is given by:

$$ADP=\frac{1}{\bar{\bar{Q}}}\int_0^{\bar{\bar{Q}}=Q(\bar{P})} P(Q')dQ',$$

$$\text{for } 0 \leqq Q \leqq \bar{\bar{Q}}$$

This expected value is the average demand price for all consumption units from zero to $\bar{\bar{Q}}$. For any output Q expected total gross benefits B are:

$$B=\frac{Q}{\bar{\bar{Q}}}\int_0^{\bar{\bar{Q}}=Q(\bar{P})} P(Q')dQ'$$

$$\text{for } 0 \leqq Q \leqq \bar{\bar{Q}}$$

For reasons analogous to those given for the zero price case, this benefit function is appropriate only for values of Q that are in the range from zero to $\bar{\bar{Q}}$. Capacity above $\bar{\bar{Q}}$ will not be used because the price $\bar{P}$ will restrict use to $\bar{\bar{Q}}$. The benefit function at this point becomes a constant, $\int_0^Q P(Q')dQ'\cdot\bar{\bar{Q}}$. Subtracting costs $C(Q)$, we obtain the welfare function that we wish to maximize:

$$(6)\quad W(Q)=\frac{Q}{\bar{\bar{Q}}}\int_0^{\bar{\bar{Q}}=Q(\bar{P})} P(Q')dQ'-C(Q)$$

---

[4] Note that the marginal cost function must intersect ADP from below to satisfy second-order conditions for a maximum.

[5] This assumes that the total conditions are met under conditions of decreasing costs.

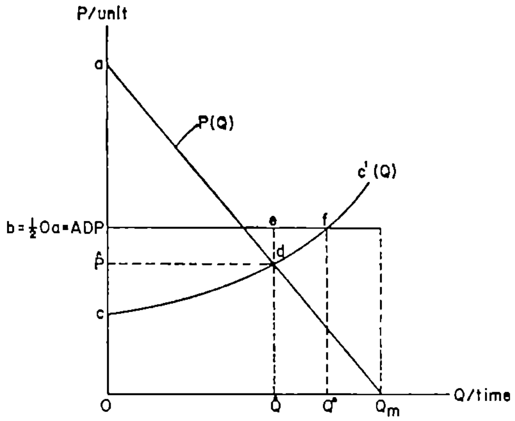

FIGURE 1. CAPACITY DETERMINATION WITH STANDARD AND NEW INVESTMENT CRITERIA
ZERO-PRICING CASE

crats, there is no practical way of allocating capacity to its highest value uses.

In the case where price is not used to allocate capacity, we assume that for any given capacity, each of the demanded consumption units from zero to Q_m has an equal probability of being satisfied. Therefore, the number of demanded consumption units is always greater than capacity, except for the case in which capacity equals Q_m. In this case, each demanded consumption unit has a probability of one that it will be satisfied.[8] Given this assumption, the expected value of a demanded consumption unit that is satisfied is given by the average demand price (*ADP*) for all demanded consumption units (see Figure 1). The average demand price can be written as:

$$ADP = \frac{1}{Q_m}\int_0^{Q_m} P(Q')dQ', \quad \text{for } 0 \leqq Q \leqq Q_m$$

For any given capacity that is less than or equal to Q_m, the expected total benefits B are determined by multiplying *ADP* times the number of demanded consumption units satisfied (capacity). Expected total benefits are represented by:

$$(3) \qquad B = \frac{Q}{Q_m}\int_0^{Q_m} P(Q')dQ' \qquad \text{for } 0 \leqq Q \leqq Q_m$$

Note that the above benefit function is only defined for values of Q in the range from zero to Q_m. For Q greater than or equal to Q_m, all demand is satisfied and there is no rationing problem. Hence, for Q greater than or equal to Q_m, the benefit function is the constant $\int_0^{Q_m} P(Q')dQ'$ and marginal benefits are zero. If we subtract costs $C(Q)$ from equation (3), we obtain the correct welfare measure (expected net benefits) when prices are not used to ration capacity. The new welfare function is represented by the following equation:

$$(4) \qquad W = \frac{Q}{Q_m}\int_0^{Q_m} P(Q')dQ' - C(Q), \qquad \text{for } 0 \leqq Q \leqq Q_m$$

Differentiating equation (4) with respect to Q and setting the results equal to zero gives the first-order condition for maximum expected net benefits:

$$(5) \qquad \frac{1}{Q_m}\int_0^{Q_m} P(Q')dQ' = C'(Q)$$

This condition represents the new investment criterion for this case in which no price is charged for the output from a public undertaking. Optimum capacity occurs at the level where the marginal cost of capacity equals the average demand price.

To complete our discussion of the investment criterion for the zero-pricing case, we must also consider the situations in which the marginal cost function does not intersect the average demand price function in the range of output from zero to Q_m (see Figure 1). First, if the marginal cost function is everywhere greater than *ADP*, the optimum capacity is zero since, for any proposed capacity, the expected benefits are less than costs. Secondly, if the marginal cost function is below *ADP* in the range of output from zero to Q_m or, because of decreasing costs, between evaluation and pricing criteria. The few who recognize the problem prefer to maintain consistency by recommending that standard evaluative criteria be used in conjunction with marginal cost pricing. We believe that the insistence on the use of standard evaluative criteria and marginal cost pricing is unrealistic. Evaluative criteria that are consistent with the zero pricing and underpricing of public products must be developed if efficiency within the public sector is to be improved.

---

[8] This assumption seems most appropriate, unless there is a definite reason for suspecting that the majority of output will go to either high willingness-to-pay users or to low willingness-to-pay users (see Gardner Brown and M. Bruce Johnson and Michael Visscher). The effect of various rationing assumptions upon our analysis will be discussed later in the paper.

In this paper, we reformulate the zero-price evaluative criterion developed by Seneca and build upon it to derive appropriate investment criteria. We then extend the analysis to the general case of underpricing, which was touched upon by Vickrey. Welfare levels for zero pricing and underpricing are compared for standard and reformulated investment criteria. Equity effects are not considered.[1] The policy implications derived from our analysis are also presented.

I. The Zero-Pricing Case

We begin our analysis with a discussion of the limiting case in which a public product's price is zero. For the output of the project in question, we have an aggregate demand price function $P=P(Q)$, where $dP/dQ<0$, $P(0)$ is finite, and there is a finite output Q_m, where $P(Q_m)=0$. If prices are used to allocate capacity, it is assumed that the definite integral of the demand price function is an adequate measure of total benefits. We further assume that operating costs are zero, and capacity is measured in terms of possible output Q for a given project scale. Hence, we have a capacity cost function represented by $C=C(Q)$. Our analysis is simplified by focusing on a single time period in which capacity depreciates instantaneously at the end of the demand period (for example, one year) for which our demand price function is relevant. Lastly, we assume that congestion costs do not exist.

Our assumption regarding congestion costs indicates that there is a direct relation between the number of production and consumption units.[2] This assumption excludes the possibility that for a given number of production units there exist alternative consumption units of varying quality, where the quality is a function of use. Our model, therefore, is developed for the case in which there is a one-to-one correspondence between output and consumption. For example, if an irrigation project is being considered, the amount of water consumed cannot be greater or less than the net amount (gross water diverted less evaporation and leakage) of water produced. Our assumption implies that, regardless of the method used to allocate the output, individuals' valuations of the output will not be altered. This is necessary to maintain independence between the demand function and the price charged.

The problem for project planners is to determine the level of output ($\hat{Q}$) (capacity) that maximizes the appropriate welfare (W) function. The welfare function used in standard analysis is represented by the following equation:

$$W(Q) = \int_0^Q P(Q')dQ' - C(Q) \tag{1}$$

To maximize welfare, we differentiate equation (1) with respect to Q and set the results equal to zero, obtaining the first-order condition:

$$P(Q) = C'(Q) \tag{2}$$

This condition represents the standard investment criterion; capacity should be chosen so that the value of the marginal unit of capacity equals its marginal cost. However, this investment criterion leads to a welfare maximum only if capacity is allocated so that only points on the demand price function with values greater than or equal to $P(\hat{Q})$ are served. The familiar marginal-cost pricing rule in which a price of $\hat{P}=P(\hat{Q})=C'(\hat{Q})$ is charged would lead to a welfare maximum, since users who do not value capacity at levels equal to or greater than the price $\hat{P}$ would be excluded. But many times no price is charged for public products and, lacking omniscient bureau-

[1] For a discussion of equity arguments for and against the underpricing of public products, see Krutilla.

[2] This relation is discussed by William Oakland.

Public Investment Criteria for Underpriced Public Products

By GENE E. MUMY AND STEVE H. HANKE*

Procedures for the design and operation of public undertakings have traditionally separated the evaluation of project benefits and the pricing of project outputs. Benefit-cost calculations have been based upon standard efficiency criteria without regard to the pricing policy utilized during the operating phase. An undertaking, whose scale has been appropriately determined by equating incremental benefits and costs, is deemed worthy of investment if its total benefits exceed costs. However, if the pricing policy that governs the sale of output is not explicitly taken into account in the benefit-cost analysis, serious errors in the estimation of benefits and, hence, the scaling of facilities will be encountered.

In practice, no widespread recognition of the effects of ultimate public project pricing policies on prior benefit calculations is evident (see Hanke). For example, the Water Resources Council has recently provided new rules for benefit-cost analysis that are far more comprehensive than any previous federal effort, but the new standards do not mention pricing policies or how they might alter the performance of public undertakings.

In the academic literature, very few have noted the dilemma created by not explicitly taking into consideration pricing policies when conducting benefit-cost analyses. John Krutilla is one of the few economists to explicitly recognize the general implications of separating evaluation and pricing procedures. In their classic benefit-cost study of the Victoria Line, Christopher Foster and Michael E. Beesley assumed that the fares imposed by the Victoria Line would make no difference in the calculated net rate of return for the project. Both Christopher Winsten and Alan Walters, in discussing the Foster-Beesley paper, correctly criticized this assumption. They argued that net benefits will be reduced by charging underground fares that exceed the appropriate marginal cost, adjusted for nonoptimal prices that existed in competing transport modes. In order to maintain consistency between evaluation and pricing criteria, Krutilla, Winsten, and Walters have recommended that standard evaluative criteria should be used in conjunction with marginal cost pricing. Roland McKean also expressed a preference for the use of standard evaluative criteria and marginal cost pricing. McKean realized, however, that prices would be set below marginal costs in some cases. In these situations, he suggested that project benefits be conservatively estimated. One of the few economists who has analytically dealt with the problem of evaluative criteria modification in the face of prices that are below marginal cost is William Vickrey. In a discussion of peak-load pricing, he recognizes that there are institutional, technical, and economic reasons why prices cannot always be set equal to the peak-load marginal cost. To maintain consistency between pricing and evaluation, Vickrey develops benefit measures for various types of nonprice rationing assumptions. Joseph Seneca has also dealt analytically with the problem of separating pricing and evaluation. He developed a measure of benefits for a given output in the extreme case in which no price is charged.

In our reading of the benefit-cost literature, we have found that most analysts ignore the problem of maintaining consistency variation measure entails a higher resultant level of welfare than the compensating variation," and that the " . . . (money value) of any given benefit to the consumer is greater for a higher level of welfare than it is for a lower." On the first count, since both measures are usually defined in relation to the same price change they can also only entail a similar welfare change, whereas the second matter appears to be a statement in sharp contradiction to Mishan's own point concerning the possible behavior of the MUY.[3]

* Assistant professor, Virginia Polytechnic Institute and State University, and associate professor, The Johns Hopkins University and University of California, Berkeley, respectively. This paper was prepared with the assistance of a research grant from the National Science Foundation, NSF-RANN, GI-34869. We wish to thank John Boland, George Borts, Gardner Brown, Paul Bugg, Anthony Fisher, Jack Knetsch, John Krutilla, Joseph Seneca, Roger Sherman, Ralph Turvey, Michael Visscher, Richard Walker, and an anonymous referee for their helpful suggestions.

Again Mishan is misleading when he states that "In the ordinal system, therefore, these two measures of the consumer's gain are *not* approximations to a more precise measure." I have already suggested that this concern with ordinality may be misplaced, but in any case all that I explained in my original paper was that neither measure corresponded exactly to the effect that Hicks and Marshall appeared to wish to evaluate, the money value of a utility change associated with a price change.[4] I would therefore hold to my original view in this matter and also in respect of Mishan's final point concerning my suggestion as to the evaluation of the effects of multiple price changes. Particularly in cases where there are both price rises and falls my suggested path of integration increases the likelihood of obtaining a measure somewhere between the (generalized) compensating and equivalent variations.

---

[3] Alternatively Mishan may mean here (but does not say) that a greater welfare increase from a given initial position will yield a greater money value of the benefits. That this is incorrect can be seen directly from the fact that the compensating and equivalent variations are just two possible different money evaluations of a given welfare change from a fixed initial position. By varying the path of integration almost any money value may be placed on any welfare change.

[4] Such a change is clearly defined by a path of integration between A and B along which income is held constant and only the price of X changes.

The Concept and Measure of Consumer's Surplus: Reply

By MICHAEL E. BURNS*

I am grateful to E. J. Mishan for drawing attention to a minor error in my recent paper, but I am unable to agree with him either as to the significance of the stated imprecision or in respect of certain other observations that he makes. The force of Mishan's comment concerns my discussion of the compensating and equivalent variations and I shall deal with this matter first, in particular with his claim that this discussion is not valid within a Hicks-Allen ordinal utility system.

My approach was first to describe the measures concerned, reinforcing this description by an illustration already widely used in the related literature, my Figure 1.[1] I proceeded to explain that the divergence between these measures reflected only that "... any evaluation of the income equivalent will depend upon the value of the marginal utility of (real) income (*MUY*) along the path on which the evaluation takes place" (p. 339). This statement draws only on the theory of line integrals as available in most advanced calculus texts, and is of course of general validity irrespective of whether one considers either a two-good or an *n*-good world and also quite independently of the behavior of the *MUY* as we shift from one utility level to another. Again, my derivation of the actual magnitudes of these two Hicksian measures that follows from the path-dependent characteristics of line integrals is quite general and completely applicable to an ordinal utility system.[2] Thus Mishan's criticism appears to be justified only in the specific case where for interpretative purposes I translated the results onto Figure 1 in a manner that precluded the possibility of the *MUY* increasing when income alone was increased. This point is well taken and the paper stands amended in this respect, but its importance to the exposition as a whole should not be overrated; indeed the sentence concerning the relative values taken by the *MUY* at positions *A*, *B*, *C*, and *D* in Figure 1 could have been omitted without affecting the content of the paper.

As it is, Mishan offers a correction concerning the ordinal interpretation of Figure 1 that I am unable to accept. Thus if the good *X* is normal in the (simply connected) region *ACBD*, and bearing in mind that we are only considering either *changes in income and/or in the price of X*, I would suggest that the *MUY* at *B* is greater than at *D* (and greater at *C* than *A*). Were the *MUY* to change in a contrary direction along an indifference curve (i.e., increase while moving from *B* to *D* or from *C* to *A*) it would always be possible to find a subregion of *ACBD* wherein *X* is an inferior good. Short of rejecting the notion that normality should be defined within a simply connected region, it would seem that Mishan's interpretation is incorrect and that my original statement needs less modification than might have appeared to be the case.

Mishan raises a number of other points that I do not find convincing. In his further discussion of Figure 1 he states that "for a fall, say, in the price of *X*, the equivalent that the difference in the Y-measures of compensating variation and equivalent variation for a change in the price of X is to be explained in terms of an income effect expressed in Y units. For a fall, say, in the price of X, the equivalent variation measure entails a higher resultant level of welfare than the compensating variation. And the Y-value (or "money" value) of any given benefit to the consumer is greater for a higher level of welfare than it is for a lower.[4]

---

* University of Manchester.

[1] Thus when Mishan refers to "... Burns' two-good system ..." he is actually referring to an illustrative device made use of by many others, including himself (1971), p. 329.

[2] A. E. Danese is one of many texts dealing with the theory of line integrals, and indeed since writing my original paper I have discovered that Shinichi Ichimura, pp. 484–85, had pointed to the relevance of such theory to this identical problem over twenty years ago. On the question of ordinal utility, the evaluation of any of the line integrals concerned requires only information of the values of x and dp along specific paths, some of these paths being indifference curves. These evaluations are therefore independent of actual utility levels, depending at most on the loci of the indifference curves.

In the ordinal system, therefore, these two measures of the consumer's gain are *not* approximations to a more precise measure. Each itself is a precise measure. If when the price of X falls, the buyer is willing to pay $10 at most in order to avail himself of the lower price, this $10 is exactly what the fall in price is worth to him. As for the equivalent variation, if the buyer were denied the opportunity of buying X at the now lower price, a sum of, say, $12 would be such as to make him just as well off as he would have been if, instead, he had been given the opportunity to buy X at the lower price.

Each measure then is a precise answer to a different, though potentially relevant question. As such, each has a clear operational value. Moreover, as Hicks and others have shown, it is the individual's demand curve that is an approximation to these two precise measures.[5]

---

[4] This is true whether the individual is responding to changes in prices as a consumer or as a producer, or as both simultaneously, and therefore whether the two measures of such changes in his level of welfare are appropriately referred to as consumer's surplus or as worker's rent or both, respectively. See the author.

[5] Accepting the area under the individual's demand curve as a reasonable approximation to the precise measures of consumer's surplus, Burns' measure of consumer's surplus of a simultaneous fall in the price of two goods i and j does not accord with that which follows from Hicks' 1956 proposal. Whether the two goods are substitutes or (as implied by the construction of Burns' Figure 2) complements, the measure of consumer's surplus is obtained by treating a simultaneous fall in prices as if they occurred in sequence, paying close attention to the *ceteris paribus*.

The Concept and Measure of Consumer's Surplus: Comment

By E. J. MISHAN*

In his recent note in this *Review*, Michael Burns' equations are correct, and his exposition in parts may be satisfactory as an interpretation of a Marshallian model of consumer's surplus, one in which the marginal utility of real income and of each good diminishes. In such a model an exact measure of consumer's surplus has to be exact in "real" terms, or in "utils." And in order to express each "util" of consumer's surplus unamibiguously as a sum of money, the marginal utility of money[1] must indeed remain constant despite any change in price that generates the consumer's surplus. In so far, then, as the marginal utility of money does not remain constant with respect to the price change in question—and, of course, it cannot do so with diminishing marginal utility of real income—any money measure of consumer's surplus derived on the (false) premise that it does remain constant can, at best, be only an approximation to some "true" util measure.

Burns' exposition cannot, however, be accepted as an interpretation of the Hicks-Allen approach to consumer theory. In their system, utility is ordinal and the marginal utility of real income, identified as the Lagrangian multiplier λ, can be constant, increasing, or decreasing, as indeed can the marginal utility of any of the goods. Thus the utility "heights" of a succession of evenly spaced indifference curves can increase or diminish in steepness[2]—the utility surface so generated being either concave, plane, or convex according as the marginal utility of real income is increasing, constant, or diminishing. But, as we all know, we do not need this utility axis in the Hicks-Allen system: we derive all the necessary theorems from the shape of the indifference curves, which shape tells us nothing at all about absolute utility.

It follows that Burns' explanation of the difference in the Y measure of compensating and equivalent variations for "normal" goods[3] is not valid within a Hicks-Allen ordinal utility system. And if we happen to have *increasing* marginal utility as total utility increases, in particular when we move from I_1 to I_2 in his Figure 1, it does not necessarily follow that the marginal utility of real income is greater at C than it is at A or at B (or less at D than it is at A or at B). All that can be said from the ordinal interpretation of the figure is that the marginal utility of Y *relative* to the marginal utility of X diminishes as Y is increased with X remaining constant (though, again, the *absolute* marginal utility of Y itself need not diminish; it can increase). And this implies that the rate of substitution $\partial Y/\partial X$ increases as Y is increased with constant X. But this is a corollary of good X being a "normal" good, defined as one for which more is bought as the consumer's budget increases.

It follows from the construction of Figure 1, in which X is depicted as a normal good, empirical results in my paper. If variables in nominal terms have to be used in the consumption function, it is essential that all variables be measured in the same units, and from this standpoint, the definition as well as the measures of accrued gains employed in my paper are correct. Accrued gains, like income and consumption, are a *flow*, and under my definition, they are expressed in the same units as these other variables. M-P's proposed adjustment to eliminate my "mismeasurement" therefore is unnecessary.[4]

---

* London School of Economics. I am grateful to Sir Roy Allen for glancing through this comment and for drawing my attention to a minor error.

[1] In an n-good cardinal utility system in which the money income $M = \sum p_i x_i$, the Lagrange multiplier λ is equal to $\partial U/\partial M$ or the marginal utility of money income. However, if a single good, say x_1, is taken as numeraire and priced at unity, the marginal utility of this good x_1 is also equal to λ (since $\partial U/\partial x_1 = \lambda p_1 = \lambda$). Thus given Burns' two-good system, if good Y is the numeraire and priced at unity, the marginal utility of Y is also equal to λ. If Y is interpreted, instead, as "all goods other than X at fixed prices," and is also regarded as numeraire equal to unity, it is necessary that the purchase price of a unit of each of these goods (other than X) add up to unity.

[2] As clearly indicated by Hicks (1946), pp. 13–16.

[3] Apparently Burns' interpretation of a normal good is one for which any increase in quantity entails diminishing marginal utility. But a normal good on the Hicks-Allen definition is, of course, consistent with marginal utility that increases, diminishes, or remains constant.

In the light of the discussion above, M-P's argument that the significant coefficient on G_t reported in my paper *could* result from the nominal variables used in empirical estimation is mere conjecture which they should verify, especially because they seem to be claiming that they have the "appropriate" data.

III. The Empirical Results

M-P are also skeptical of my assertion that the empirical results in the wealth approach are much sharper because it is ". . . based primarily on a comparison of the Durbin-Watson statistics" (p. 700, fn. 1). In my paper I said:

> The results are much sharper than in the income approach: the Durbin-Watson statistic suggests serial independence of residuals in all cases, W_t^* and Y_t^* are highly significant, the coefficients have the expected signs (positive), and their magnitudes are not affected much by whether accrued or realized gains are included in the equation. The normal rate of return on wealth ($\hat{\beta}=k\beta/k$) is estimated between .06 and .08, which seems quite reasonable. All in all, equation (6) appears to be much better specified than equation (4). [p. 875]

M-P's statement, to say the least, is a grossly unfair representation of my position. In response to their point that the Durbin-Watson statistic might be biased because of a lagged dependent variable in the consumption function, I present below the Cochrane-Orcutt estimates of equation (6) for accrued gains (see fn. 18, p. 873 of the original paper).

$$\underset{(-0.34)}{C_t = -\,3.052} + \underset{(6.17)}{0.790Y_t^w} + \underset{(2.89)}{0.051W_t^*}$$

$$SEE = 1.96, \quad R^2 = 0.999, \quad D.W. = 2.17, \quad \hat{\rho} = \underset{(-0.11)}{-\,0.031}$$

$$C_t = \underset{(21.87)}{0.748Y_t^w} + \underset{(9.27)}{0.057W_t^*}$$

$$SEE = 1.78, \quad R^2 = 0.999, \quad D.W. = 2.20, \quad \hat{\rho} = \underset{(-0.22)}{-\,0.063}$$

where *t*-values are enclosed in parentheses. It is obvious that these results are almost the same as those reported in my paper. Also note that $\hat{\rho}$ is not significantly different from zero.

nonfarm real estate were estimated by subtracting net capital formation from change in net worth during a year ($W_t - W_{t-1}$), but the procedure for estimating gains on corporate stock was different and more complicated. It involved the use of a stock price index and a series of adjustments to correct for possible errors in the data series. See the author (1973) for details.

[4] M-P's proposed measure is

$$G_t' = W_t - \left(\frac{P_t}{P_{t-1}}\right) W_{t-1} - \left(\frac{P_t}{\overline{P}_t}\right) I_t$$

It will, in effect, express accrued gains in prices prevailing at a *point* in time, the end-of-year. But the other flow variables in the consumption function, namely C and Y, are expressed in prices prevailing at *different points* during the year: these are simply totals of quarterly or monthly data without any adjustments for changes in price level. For example, the national accounts estimates of personal income in current prices are $Y_t = Y_{t1} + Y_{t2} + Y_{t3} + Y_{t4}$, and not

$$Y_{t1}\left(\frac{P_4}{P_1}\right) + Y_{t2}\left(\frac{P_4}{P_2}\right) + Y_{t3}\left(\frac{P_4}{P_3}\right) + Y_{t4}$$

as consistency with the M-P measure of accrued gains would require.

Clearly, our reference must be to savings and dissavings realized for the purpose of shifting expected consumption over time, and we must seek the best such measure derivable from the data at hand. Given the *BLS* breakdown of expenditures, that measure excludes gifts or contributions and personal-insurance premiums, even though part of the latter are true savings which, ideally, we would want to retain. The matter of whether these expenditures should be added to consumption (as done by Thurow under his second option) or subtracted from income is to be resolved empirically: Since the insurance /contributions total varies roughly in proportion with after-tax income, but not so with consumption, the subtraction from income is more consistent with our specification of the analytic model.

Accordingly, the empirical work in Section IVD was redone, using after-tax income net of personal-insurance premiums and contributions. The income measure was further corrected by addition of "other money receipts," a category left out of the *BLS* definition of money income.[21] The results are similar to those obtained in *D*, although the maximum excess of desired over actual consumption occurs even later in life and is of lesser magnitude than under the initial definition of income.[22] This confirms the suspicion that, for the average-income household, ***institutional obstacles to additional borrowing are experienced in the years when the cost of supporting and educating dependents is at its highest, and when expensive comforts have become an important condition for the enjoyment of life.***

F

The effect of two biasing factors identified in the course of the analysis accounts for slight inconsistencies observed in the estimates: (a) a desired consumption rising above actual in the oldest age class (under the adjusted estimate of Section IVE only), and (b) a desired consumption slightly under actual in the youngest age class.

In general, the existence of any discrepancy between desired consumption d_A and intended consumption $\hat{c}_A$ at the zero-saving observation for age A, generates an estimate $\tilde{g}_A$ in (29′) that deviates from its true value $g(A)$ by:

$$\tilde{g}_A - g(A) =$$

$$\Delta_A \frac{\theta_A(C_A)}{(1-p)+p[y_A^* + r(A)]/[F(A)+r(A)]}$$

where Δ_A is the discrepancy $(\hat{c}_A - d_A)$ and $\theta_A(C_A)$ is the value of the biasing function introduced in (16), both at the zero-saving observation.[23] The ratio multiplying Δ_A does not deviate much from 1, since the denominator has an empirical range of 0.9 to 1.5 and $\theta_A(C_A)$ can be assumed close to 1. Roughly speaking, then, the bias of the estimate $\tilde{g}_A$ is of the same order as the discrepancy Δ_A.

(a) It was shown in Section II that we generally have $\hat{c}_A > d_A$, or $\Delta_A > 0$ at actual zero-saving points, meaning that the estimated profile of desired consumption is biased upward. This bias would be especially strong for later-life estimates, where zero saving occurs in the lower range of income profiles after a long history of constrained dissaving.

(b) A reverse (and likely larger) bias affects estimates in the youngest age groups, where zero-saving observations occur in the high range of income profiles. As pointed out in Section IIID, zero-saving *observations* imply an intended dissaving if the income profile is high, and an intended positive saving if the profile is low. The implication in the first case is that desired consumption is above actual, i.e., $d_A > \hat{c}_A$, or $\Delta_A < 0$, as long, that is, as we can assume the discrepancy thus created to exceed that identified above. This suggests a downward bias of the estimated profile of desired consumption for the youngest age classes.

---

[21] "Other money receipts" include inheritances and occasional large gifts of money less taxes and associated expenses; and net receipts from the lump-sum settlement of fire and accident insurance policies.

[22] Zero-saving incomes (under the new income definition) were obtained through careful interpolations of available class averages. An ambiguity occurs in the "under-25" age interval, where savings fluctuate between positive and negative values over four income classes. Fortunately, the estimate of desired consumption for that age interval is relatively insensitive to variations of the zero-saving income in its possible range. Another difficulty occurred in the estimation of $r(A)$, which was computed as the average of point estimates for the 10th percentile and 90th percentile income profiles only. Point estimates for the 50th percentile were eliminated because of their excessive sensitivity to observational error (the denominator $W^i - 1$ in the estimation formula (fn. 19) is a low $-.086$).

[23] The expression for $g(A)$ is easily obtained by repeating Section IVD's computations with $\hat{c}_A = d_A + \Delta_A$.

It is not unrealistic to expect that, in the middle range of ages, the two identified biases approximately cancel one another, so that the estimated profile of desired-consumption can be accepted with a reasonable degree of confidence.[24] Nevertheless, the conclusions are in need of testing against more direct evidence of individual saving behavior under actual or experimental variations in household access to consumption loans.

---

[24] In common with the work of Thurow and his reviewers, no effort was made to adjust cross-sectional data on income and consumption by age interval for average income growth over time. This is not likely to affect the measure of discrepancy exhibited in Figure 6, but it does mean that both the desired and the actual consumption profiles are, in fact, tilted upward on the upper-age side.

The Optimum Lifetime Distribution of Consumption Expenditures: Reply

By LESTER C. THUROW*

There are several levels upon which a reply might be written to Andre Daniere. Given what I presume is a high decay rate in the reader's interest in comments and replies let me start with the final results and work backwards. Qualitatively we agree. Both Daniere's methods and my methods lead to the need for some redistribution of lifetime consumption expenditures toward younger ages. Daniere says that we disagree quantitatively ("the gap is small in relation to that calculated by Thurow"). In my original article the optimum redistributions were $31,802 under the first definition of savings and $21,618 under the second definition of savings out of an expected lifetime income of $342,246. Since Daniere does not choose to tell us the size of his optimum redistributions, I do not know whether his quantitative estimates lie outside my range of Baysian reasonableness. Eyeball integration of Figure 6 (his final results) leads me to the conclusion that he also has a substantial amount of redistribution.

Perhaps even more to the point, the net result of all of Daniere's modifications of my original estimation technique is to give a result that is, as he admits absurd (see Section IVE). He states, "One disturbing feature of the desired-consumption profile estimated in the previous section is that it exceeds actual consumption over a range (age 25–45) in which income is itself higher than consumption: If the average-income household wishes to consume more in that range, why does it not do so by spending more of its income?" Why indeed? There is no reason for actual consumption to fall below desired consumption if desired consumption is itself less than actual income. He does not even try to explain the even greater absurdity of estimating desired consumption to be less than actual consumption in the earliest age ranges (see Figure 6).

To escape from his embarrassment of having estimated results that are logically impossible, he suddenly decides to shift from my first definition of savings to a strange transformation of my second definition of savings. In my original article zero savings was defined in two ways. 1) Zero savings occurs when after-tax money income is equal to expenditures for current consumption, and 2) zero savings occurs when after-tax money income is equal to expenditures for current consumption plus gifts, contributions, and personal-insurance payments. In the second case gifts, contributions, and insurance payments are considered consumption expenditures rather than savings. Daniere, however, wants to subtract gifts, contributions, and insurance payments from income rather than add them to current consumption expenditures. (Which you do makes a difference since estimated lifetime consumption expenditures must be adjusted up or down (see fn. 14 in my original article) to be brought into equality with actual lifetime incomes.)

Gifts, contributions, and insurance payments might be considered savings or they might be considered consumption, but they clearly are not vanishing income. Why then does Daniere want to treat them as vanishing income? His own justification does not make any sense. "The matter of whether these expenditures should be added to consumption (as done by Thurow under his second option) or subtracted from income is to be resolved empirically: Since the insurance/contributions total varies roughly in proportion with after-tax income, but not so with consumption, the subtraction from income is more consistent with our specification of the analytical model." What this means I leave for others to decipher. In my understanding of economic accounting there are savings or investment expenditures and consumption expenditures. Income is by definition equal to the sum of the two. There is nothing called vanishing income.

---

* Massachusetts Institute of Technology.

Why then this peculiar invention of vanishing income? I know of only two possible explanations. To treat gifts, contributions, and insurance in the normal way would be to obtain another absurd result or an estimate closer to my original results.

Given what are admitted to be silly results, the only real questions revolve around which of his three basic adjustments (tilt, permanent income, and the inequality between lifetime income and consumption) causes the absurd results.

The easiest of these to deal with is tilt. As Daniere correctly points out, any restrictions on actual dissaving in early years will raise observed consumption in later years as individuals attempt to compensate for their lack of consumption in early years (see his Figure 2). This will distort the calculated relationships between actual consumption and desired consumption. What Daniere neglects to point out, however, is the kind of bias introduced by a failure to allow for the current impact of past disequilibria. Early constraints on dissavings will raise consumption levels in middle and later years and thus my estimates will overestimate—not underestimate—the amount of consumption that the family would ideally like to do in its middle and latter years. Thus a correction for tilt *must* increase the amount of desired redistributions.

How then can you square the known direction of the bias with the empirical measures of the bias at the end of his Section IVD? I can only assume that Daniere made an algebraic error and reversed the signs so that we made exactly the opposite correction for those that should have been made.

But there is something else wrong with Daniere's tilt calculations. For some unknown reason he assumes that the bias is zero at 50 years of age. The bias could be zero at the initial age or at the final age, but it cannot be zero at a middle age. At the initial age earlier disequilibria cannot affect consumption since there are no earlier disequilibria by definition. At the final age disequilibrium can have no impact since the individual has had his entire lifetime to correct for the early disequilibria. Thus his tilt corrections are wrong with respect to both sign and lifetime pattern.

Daniere's second supposed correction is for neglecting the difference between permanent and transitory income. Here it is not clear whether Daniere is working with a permanent income model where the expected lifetime value of transitory income is zero or where the expected lifetime value of transitory income is positive. In the second case lifetime optimization is clearly a more difficult problem than the one I proposed since the individual does not know his or her lifetime income. Obviously you cannot optimize vis-à-vis an unknown constraint. If individuals systematically overestimate lifetime incomes, early consumption expenditures will be too high relative to later consumption expenditures and if individuals systematically underestimate lifetime income, early expenditures will be too low. As a result my estimates are only biased toward too much redistribution if you believe that individuals systematically overestimate lifetime incomes. If lifetime transitory incomes are positive, then my estimates are too low, not too high.

But let's go back to the hypothesis that the expected lifetime value of transitory income is zero. In this case there should be no bias in my results. The distinction between permanent and transitory income leads to conclusion that there will be too many individuals in the upper or lower tails of the distribution at each age but it does not affect the mean of the distribution. Since I was working in the middle ranges of the income distribution and with groups of individuals, no bias is introduced. The bias would be important if I were working with individual data, but I am not. Presumably those that are zero savers by accident (transitory income placed them in a nonoptimal consumption class) cancel each other out and the observed income of the class of zero savers has not been biased by the existence of these accidental zero savers.

The third correction is designed to take account of the "fact" that lifetime consumption does not equal lifetime income for high income classes. Several observations need to be made. First the observation is deduced from the fact that the 90th percentile of the income distribution has a lifetime pattern of consumption that is always below its income (see Figure 3). Daniere forgets his permanent-transitory distinction and the easy explanation that the 90th percentile is not necessarily the same families. Second, bequests at death can be regarded as a form of consumption so that individuals desire to consume a lot at the point of death. If this is true, the appropriate correction is not to raise desired consumption during the middle years, but to raise consumption at death. Assuming a positive rate of time preference this would lead to more saving during the middle years to increase consumption at death. Once again the failure to allow for this possibility means that my estimates are biased toward too much consumption in the middle years, not too little. Third, the middle income family—the family that I am concentrating upon—does not leave a substantial amount of assets at death. Its lifetime consumption does seem to be near its lifetime income and therefore a correction is not necessary for a middle income family.

I also agree with Daniere that there is a problem with my estimation technique if you assume that the basic lifetime pattern of tastes changes as lifetime incomes rise or fall. This is a possibility that was discussed in the original article and to some extent investigated empirically (see fn. 14 in my article).

Where does this leave us? Since my original article rested on some strong assumptions, I would be the first person to acknowledge a better calculation that succeeded in lifting some of those assumptions. Unfortunately Daniere's calculations are not an improvement.

A Model of a Highway System Financed by a Trust Fund

By E. G. DAVIS AND J. E. OLSON*

> What made the road in general was man's necessity of passing from one point to another; but what made the Highway was the Vehicle.
>
> It was when man began to extend his carrying capacity (and perhaps his speed) by the creation of the Vehicle that the road took on a special form and became what it has remained among us: the Highway. The cause determines the effect, but, what is more, the effect is contained in the cause.
>
> [*Hilaire Belloc*, p. 1]

Mutual interdependence between the vehicle and the highway did not stop with their creation; in the United States, this interdependence has been institutionalized by legislative action. Highway construction and maintenance are financed by vehicle-related taxes levied at both federal and state levels which are, in the main, dedicated to these purposes by law.[1] Chief among these is the tax on gasoline.[2]

There is, in addition, a behavioral relationship between the vehicle and the highway: vehicle usage is presumably affected by the size and quality of the existing highway system. Moreover, revenue from gasoline taxes would be determined primarily by vehicle usage. The fact that the revenues are dedicated to highway purposes by law completes what is, in essence, a dynamic process.

In this paper we present a simple model of the dynamic relationship between highway size and vehicle usage and attempt to estimate its parameters.

I. The Model

Our model of the process of highway construction and maintenance differs from reality in two major respects: we assume one national trust fund rather than separate state and federal funds, and we assume the only source of revenue for the fund is the tax on gasoline. As a result, total gasoline tax revenue R will be, by definition, the tax rate per gallon T times total gasoline consumption. This relationship can be expressed as:

$$R \equiv \frac{TV}{e} \tag{1}$$

where V represents highway usage in vehicle miles and e, average gasoline efficiency measured in miles per gallon.

From the fact that gasoline tax revenues are dedicated by law to highway expenditures we obtain:

$$R = \mu H + k\frac{dH}{dt} \tag{2}$$

where H represents the size of the existing highway system; k, the average cost of construction per mile of new highway; and μ, the average maintenance cost per mile per year to prevent existing highway from deteriorating.[3]

With the usual *mea culpa* qualifications we would like to acknowledge the assistance of A. Reza, M. Spiro, and R. Bhaskar, of the University of Pittsburgh, S. B. Park of Carleton University, and the referee.

[1] Law now permits some use of the Federal Highway Trust Fund for mass transit. However, the amounts are rather small and the uses quite limited.

[2] William Shannon states: "Forty-five of the 50 states have either constitutional or statutory restrictions on the use of gasoline taxes for any purposes except highway construction and maintenance" (p. 120). Beginning with the Federal-Aid Highway Act of 1956, federal gasoline tax revenues were dedicated to financing highway construction.

[3] In practice, not all earmarked funds have been expended so that a surplus has been accumulated. The model could be adjusted to include a parameter multiplying R in equation (2) representing the fraction of current funds expended, and the analysis would not be

Highway usage is plausibly affected by a variety of factors in addition to the size of the highway system. General economic conditions affect the demand for vehicular transportation since transportation is both an input in production and a form of consumption. Recently, of course, the availability of gasoline has had a dramatic effect. Changes in the price of gasoline may also be important. In the long run, demographic and structural factors will play a role. For the purposes of this model, all factors affecting highway usage except the size of the highway system (and later, economic conditions) are considered exogenous.

The relationship between highway usage and highway size is expressed as:

$$(3) \quad V = h(H), \ h' > 0, \ h'' < 0, \ h(0) = 0$$

The assumptions about the derivatives of h can be rationalized by a diminishing returns argument. Although more roads generate greater usage, the most needed roads are built first.

Combining these three equations and assuming an initial value for H, the dynamic behavior of the model is described by:[4]

$$(4) \qquad \frac{dH}{dt} = \frac{1}{k}\left[\frac{Th(H)}{e} - \mu H\right]$$

The model has a unique, stable equilibrium,[5] given the assumptions of equation (3), if:

$$(5) \qquad \lim_{H \to 0} h'(H) > \frac{e\mu}{T}$$

If this inequality were not satisfied, even with an arbitrarily small highway network, revenues would not cover maintenance required to maintain the system.

The comparative static behavior of the model is easily seen. The higher the tax rate or the less efficient the vehicles, the greater the tax revenue and the larger the equilibrium highway system. The greater the maintenance costs, the smaller is the road network. Construction costs do not affect the equilibrium size; instead they determine the adjustment time to equilibrium.

II. Estimation

In this section an attempt is made to estimate the vehicle-usage function and to predict the size of the equilibrium highway system.

We postulate as a model for usage that:

$$(6) \qquad V = A - BH^{-\alpha} + CY$$

H enters in this exponential form because it is only reasonable that as H goes to infinity, usage should approach a finite limit.[6] Moreover, of all the other factors which may affect highway usage besides highway size, the state of the economy, measured by the level of real GNP (Y), would appear to be the most important variable in explaining year to year changes. With B and α constrained to be positive, this functional form is consistent with the assumptions of equation (3).

We wished to estimate this relationship for the period 1950 to 1969.[7] However, the time trend common to V, H, and Y makes direct estimation unwise. To minimize this problem first differences were used:

$$(7) \qquad V_t - V_{t-1} = -B[H_t^{-\alpha} - H_{t-1}^{-\alpha}] + C[Y_t - Y_{t-1}]$$

This equation was then estimated by a nonlinear least squares technique with the re-

---

substantively affected. It should be noted that in our model, new construction is a residual determined by the funds remaining after the necessary maintenance has been financed.

[4] The parameters k, T, e, and μ are taken to be constants. If these parameters behaved systematically with respect to time, there would in general be no finite, nonzero equilibrium.

[5] A precise characterization of behavior in the region to the right of the equilibrium would require an assumption about the rate at which highways crumble into nonexistence when they are not maintained.

[6] H would affect usage partly by reducing the money cost of a trip and partly by reducing the travel time per trip. Both types of costs would have a positive lower bound as H increases.

[7] If the years 1973 and 1974 were included in our estimation, then the availability and price of gasoline would also be of major significance in explaining usage. Bearing in mind these factors, one would want to reestimate our results before assigning much significance to our subsequent extrapolation for the equilibrium highway size.

sults as follows:[8,9]

$$(8)\quad V_t - V_{t-1} = -14{,}900[H_t^{-.04337} - H_{t-1}^{-.04337}] + 1.008[Y_t - Y_{t-1}], \quad \overline{R}^2 = .91$$

These estimates for B, α, C were then used in equation (6) and the difference between the actual and predicted values for V was taken as an estimate of the intercept A. The 19 estimates, so obtained, were then averaged to yield a point estimate for A of 11,945.[10]

It is possible to use this usage relationship to extrapolate to find an estimate for the equilibrium highway size (when revenues balance maintenance expenditures) if the parameters and Y are held constant. This involves solving for H_B from the equation:[11]

$$(9)\qquad A - BH_B^{-\alpha} + CY = \frac{e\mu}{T} H_B$$

This yields a value for H_B of 5.6 million miles, approximately double the current length.

III. Concluding Remarks

We have shown, with reference to the highway system, that use-financed construction programs imply a differential equation solution for capacity. Moreover, it is possible to estimate a usage relationship and obtain a tentative idea of future behavior by extrapolation.

One can generally criticize the earmarking of revenues from any tax as an unnecessary barrier to the efficient allocation of resources. The gasoline tax is no exception. However, assuming that some earmarking of tax revenues will continue, knowledge of the implicit time path of capacity would, at least, be useful to a policy maker with responsibility for choosing tax and expenditure parameters.

[8] Y was taken to be the level of real *GNP* in billions of dollars and V and H were represented by the series for vehicle miles (in billions per year) and miles of surfaced roads and streets (in tens of thousands), respectively.

[9] The program (Gaushaus from the University of Wisconsin Computing Center) prints out very approximate 95 percent confidence intervals based on a linear approximation in the neighborhood of the final parameter values. The intervals were $\pm 2.23 \times 10^6$, ± 1.205, and $\pm .293$, for B, α, and C, respectively. The large intervals for B and α are an unfortunate consequence of fitting a term of the form aX^b. When a linear regression was run with α set at .04337, the same coefficients were obtained (of course) for B and C and the corresponding t values were 3.60 and 7.19, respectively.

[10] This procedure seems appropriate so long as the random disturbance in equation (6) has zero expectation. The estimates for A ranged from a high of 11,989 to a low of 11,930.

[11] We used 1968 values for the parameters: T was \$.1062 per gallon; μ, \$2,065 per mile; e, 12.25 miles per gallon. Y_{1968} was 706.6 in billions of 1958 dollars.

Optimal Advertising: A Note

By DAVID WEBER*

In an article which appeared some twenty years ago, Robert Dorfman and Peter Steiner derived the necessary conditions for optimal advertising expenditures for the case of a firm which aims to maximize total profit and which is isolated from the competition of rivals. Their result called for that amount of advertising for which the marginal value product of advertising equals the absolute value of the partial price elasticity of demand. It may be shown that this result holds for other market circumstances as well (see my dissertation).

I should now like to demonstrate that an interesting variant of the Dorfman-Steiner condition holds if demand uncertainty is incorporated into an otherwise straightforward leader-follower model, as first developed by Stackelberg. I focus on the follower firm whose objective is assumed to be the maximization of expected total profit, to be defined below. In the interests of mathematical tractability, the demand function of the follower is assumed to be:

$$Q_2 = A^{\delta} P_2^{\alpha} P_1^{\sigma} a_2^{\beta} a_1^{\gamma} v \tag{1}$$

where v is a uniformly distributed random variable such that the probability density function

$$f(v) = \frac{1}{k} \qquad \text{if } 0 \leq v \leq k \tag{2}$$

$$f(v) = 0 \qquad \text{otherwise} \tag{3}$$

(I have chosen to use such an error, not only because manipulations are not difficult to perform, but, in addition, a uniform error is used in the model developed by Edwin Mills which I am following, and, in light of the general statement of my model, it is sufficient to permit the incorporation of demand uncertainty.) Also, Q_2 is the quantity demanded of the follower's product, P_2 is the price set by the follower, a_2 is the level of advertising set by the follower, P_1 is the price set by the leader, a_1 is the level of advertising set by the leader, and A measures real disposable income per capita. Following the framework developed by Mills, the follower is presumed to assume that for any price-output-advertising combination he might set, there is a chance he will be short by some amount, the mean amount of shortage for any such combination depending on the probability distribution of demand.

The follower's expected profit function is:

$$E(\pi_2) = E(P_2Q_2) - c_2z_2 - a_2 \tag{4}$$

where z_2 is the output of the follower, not likely to be the same as Q_2. That is, the follower's maximization problem depends on three independent decision variables, an optimal price-advertising combination no longer implying an optimal output. (Mills presumes that the output decision is made before the actual quantity demanded for the period, i.e., v, is revealed.) Now the first term on the right-hand side of (4) is expected total revenue, which Mills defines to be the difference between the value of expected demand and the value of expected shortage. Only if each possible quantity demanded (at a given price-advertising combination) could be sold would the value of mean demand and expected total revenue be the same; those quantities demanded that could not be satisfied from a given output should not be included in the follower's calculation of expected total revenue. Substituting the demand and density functions defined above into the follower's expected profit function, we have:

$$E(\pi_2) = A^{\delta} P_2^{\alpha+1} P_1^{\sigma} a_2^{\beta} a_1^{\gamma} \frac{k}{2} \tag{5}$$

(over)

---

* U.S. Coast Guard Academy. This note is based on my doctoral dissertation. I thank a referee for comments, but accept full responsibility for any errors that remain.

$$- P_2 \int_{z_2/f_2}^{k} \frac{f_2 v - z_2}{k}\, dv$$

$$- c_2 z_2 - a_2$$

where

$$(6) \qquad E(v) = \frac{k}{2}$$

$$(7) \qquad f_2 = A^{\delta} P_2^{\alpha} P_1^{\sigma} a_2^{\beta} a_1^{\gamma}$$

The value of the integral is the mean amount of shortage expected when P_2, a_2 is set and z_2 is produced. Shortage will occur when actual demand exceeds output, i.e., when $f_2 v > z_2$, or for those values of the random variable greater than z_2/f_2.

If we now take the partial derivative of (5) with respect to the follower's three decision variables and set each equal to zero, the resulting set of first-order conditions may be manipulated to give the desired result, a variant of the Dorfman-Steiner theorem for optimal advertising expenditure. This three-equation system may be written compactly as follows:

$$(8) \qquad f_2 \frac{k}{2} + P_2 \frac{k}{2} \frac{\partial f_2}{\partial P_2} = g_2 + P_2 \frac{\partial g_2}{\partial P_2}$$

$$(9) \qquad P_2 \left[1 - F\left(\frac{z_2}{f_2} \right) \right] = c_2$$

$$(10) \qquad P_2 \frac{\partial f_2}{\partial a_2} \left[\frac{k}{2} - \left[\frac{k^2 f_2^2 - z_2^2}{2kf_2^2} \right] \right] = 1$$

where $g_2 = \int_{z_2/f_2}^{k} \frac{f_2 v - z_2}{k}\, dv$

and $F(v)$ is the cumulative distribution function corresponding to $f(v)$. Multiplying the second term on the left-hand side of (8) by f_2/f_2 and substituting for $\partial g_2/\partial P_2$, (8) becomes:

$$(11) \quad f_2 \frac{k}{2} + h f_2 \frac{k}{2} = g_2 + P_2 \frac{\partial f_2}{\partial P_2} \left[\frac{k^2 f_2^2 - z_2^2}{2kf_2} \right]$$

where h is the partial price elasticity of demand of the follower's riskless demand curve. Multiplying the partial derivative on the right-hand side of (11) by f_2/f_2 and substituting from (10), (11) becomes:

$$(12) \quad f_2 \frac{k}{2} (h + 1) = g_2 + f_2 h \left[\frac{\mu \frac{k}{2} - 1}{\mu} \right]$$

where $\mu = P_2(\partial f_2/\partial a_2)$, which is what Dorfman and Steiner call the marginal value product of advertising. Equation (12) may be manipulated into:

$$(13) \qquad \frac{h}{\mu} = \frac{g_2}{f_2} - \frac{k}{2}$$

With uncertainty present, the relationship between h and μ depends on the price and output set. If we assume that P_2 and (or) z_2 is set so high that mean shortage g_2 is zero, the condition for optimal advertising is very similar to that derived by Dorfman and Steiner in which case certainty is assumed. (Note that $\mu k/2$ may be interpreted as the mean marginal value product of advertising, with $f_2 k/2$ being mean demand.) But if g_2 is not zero, which Mills argues is likely, h will be less than $\mu k/2$ in absolute terms at the optimal level of advertising since $g_2 \leq f_2 k/2$. (Note that $g_2 = f_2 k/2$ only if $z_2 = 0$.)

I conclude by demonstrating that associated with this result is the conclusion that with uncertainty present in the manner described, a smaller amount of advertising will be optimal. First we note that (10) may be interpreted as requiring that at the optimal level of advertising, the expected value of the marginal value product of advertising is greater than the marginal cost of an extra dollar of advertising, which is one, or that a fraction of the expected value of the marginal value product of advertising equals one at the optimal level of advertising. Second, it may be shown that if the assumption of uncertainty is dropped while all other features of the model remain intact, one of the two resulting first-order conditions requires that the marginal value product of advertising be one. If $\beta < 1$ per second-order conditions for either model, the marginal value product of advertising will be smaller only at a higher level of advertising. A rationale for less advertising being optimal under uncertainty is that because there is a positive probability of shortage, the follower is reluctant to advertise as much for fear that some of the demand which will be generated will not be able to be satisfied, given the output produced.

On the Effects of Fiscal and Monetary Policy: Completing the Taxonomy

By LAURENCE H. MEYER AND WILLIAM R. HART*

In a recent issue of this *Review*, Bent Hansen presented a taxonomic discussion of the effects of monetary and fiscal policies. Hansen suggests that the analysis "... bears directly upon the controversy between Keynesians and Monetarists" (p. 546). A central issue in this debate is the potency of bond financed fiscal operations and the nature and quantitative significance of the "crowding-out" effect. Complete crowding out occurs when an increase in government expenditures crowds out an equivalent amount of private expenditures, leaving aggregate demand and, hence, income unchanged. According to the Monetarists, this crowding out of private expenditures reflects the crowding out of private borrowing by the increased government borrowing. Hansen's model is designed to capture this interaction of government and private spending and borrowing and, on the surface, appears well suited for this purpose. It includes both government and private bond markets and imposes financing constraints on both government and private investment expenditures. Nevertheless, an increase in the supply of government bonds has no direct impact on the supply of or demand for private loans.

The unusual feature of Hansen's model which prevents it from capturing this effect is the lack of a direct connection between the two bond markets. Because all private investment is financed through bank loans and because banks do not hold government bonds, Hansen's model effectively dichotomizes the financing of private investment and the financing of government expenditures. As a result, the government does not compete directly with the business sector for sources of funds in the financing of expenditures.

In this comment we will modify Hansen's model so that it can capture the direct portfolio impact of an increase in the supply of government bonds on the private loan rate. First we will present Hansen's model and consider its relation both to the Monetarist view of the crowding-out effect and to recent attempts to model this effect.

I. Hansen's Model

The general form of the model used by Hansen in discussing the taxonomy is shown below.

$$(1)\qquad Y = I + C + G$$

$$(2)\qquad C = c_1(Y - T + B) + c_2(M^n + \alpha M^b + B/r_g) + c_3; \quad c_1 > 0, \quad c_2 > 0$$

$$(3)\qquad I = i_1 r_b + i_2 Y + i_3; \quad i_1 < 0,\ i_2 > 0$$

$$(4)\qquad T = t_1 Y + t_2; \qquad t_1 > 0$$

$$(5)\qquad M^n = nY; \qquad n > 0$$

$$(6)\qquad \alpha M^b = m_1(r_g - \mu r_b) + m_2 Y + m_3 B/r_g; \quad m_1 < 0, \quad m_2 > 0, \quad m_3 > 0$$

$$(7)\qquad \bar{K} + I = (\alpha - 1)M^b + L^b$$

$$(8)\qquad L^b = \beta_1(r_b - \bar{r}) + \beta_2; \qquad \beta_1 > 0$$

All variables in the model are as defined by Hansen: Y is income, I investment, C consumption, G government expenditures, T tax revenue, B is the number of government bonds held by the private sector (perpetuities with \$1.00 interest payments per period), M^n currency in circulation, M^b commercial bank deposits at the central bank, r_g bond market rate of interest, r_b commercial banks' loan rate, α inverse of the required reserve ratio, μ the ratio between commercial banks' deposit and loan rates, $\overline{K}$ initial private stock of capital, L^b rediscounts and advances to commercial banks, $\bar{r}$ the central bank's discount rate, D_0 the budget deficit at the beginning of the period.

---

* Assistant professor, department of economics, Washington University, St. Louis, and instructor, department of economics, Miami University, Ohio, respectively. We would like to thank Bent Hansen for providing us with his worksheets detailing the computation of his multipliers. We also received helpful comments from the participants in the Research Workshop in Money and Banking at Washington University. An appendix containing the computation of the multipliers discussed in this paper is available upon request.

The model is completed with the addition of a public sector budget constraint. Two possible public sector budget constraints are considered by Hansen. The European constraint reflects an institutional setting in which the central bank issues currency, makes loans to and keeps deposits for commercial banks, and acts as a banker for the government. This constraint takes the following form:

$$\text{(9)} \quad dM^n + dM^b = dG - dT + dB + D_0 - dB/r_g + dL^b$$

The *U.S.* constraint reflects an institutional setting in which the government does not use the central bank and therefore is forced to finance its deficits and surpluses exclusively through bond transactions with the private sector. This constraint takes the following form:

$$\text{(9a)} \quad dM^n + dM^b = dL^b - dB_{CB}/r_g$$

$$\text{(9b)} \quad dB_{Tr}/r_g = dG - dT + dB + D_0$$

$$\text{(9c)} \quad dB = dB_{CB} + dB_{Tr}$$

where $-dB_{CB}$ is the number of government bonds bought by the central bank in the open market and dB_{Tr} is the number of bonds sold by the Treasury to the private sector.

Although the public sector budget constraint is not new to economic analysis, Hansen's discussion is unique because he points out that some knowledge of the institutional set-up of the economy is required to determine the precise specification of the constraint. The specific form of the budget constraint, in turn, builds into the model the limitations in policy options imposed by institutional arrangements. A second unique and innovative feature of Hansen's model is the requirement that all investment be financed through bank loans. This requirement is embodied in equation (7), the equilibrium condition in the bank loan market. Hansen's model thus extends the logic of the public sector budget constraint to the private sector.

Equations (1)–(8) and (9) represent what Hansen calls the European model, while equations (1)–(8) and (9a), (9b), (9c) represent the *U.S.* model. Our principal concern is with Hansen's failure to incorporate the role of credit markets in the crowding-out effect. Therefore we concentrate on the effects of a bond financed increase in government expenditures. Using the European version of the model, G, t_1, B, $\bar{r}$, and α are selected as policy instruments, and their corresponding differentials represent the discretionary measures taken. To determine the impact of a bond financed fiscal operation, we let all discretionary policies and autonomous changes, other than dG and dB, equal zero. Solving the system for dY, the bond financed operation yields:

$$\text{(10)} \quad dY = \frac{1}{\Delta} \cdot \Big\{ \underset{I}{dG} + \underset{II}{c_1 dB + c_{\_}dB/r_g} + \underset{III}{dB/r_g(\delta_2)} \Big\}$$

where $1/\Delta =$ the basic multiplier and is assumed positive and

$$\delta_2 = \frac{m_3 c_2 (B/r_g^2)}{m_1 - m_3(B/r_g^2)} < 0$$

The multiplicand consists of three terms, each one measuring an impact on output. Term *I* is the direct impact on demand by virtue of the fact that G is a component of aggregate demand. Terms *II* and *III* represent two impacts resulting from the increase in the supply of government bonds. The total impact on income is ambiguous.

In light of the arguments by Monetarists and recent work concerning the financing of government expenditures (see articles by William Silber and Meyer), this does not appear to be too startling a result, and one might be led to believe that terms *II* and *III* are, in fact, capturing the impact of credit markets in the crowding-out effect. This result does appear quite startling, however, if we let c_2, the marginal propensity to consume out of wealth, and the marginal propensity to consume out of interest payments[1] go to zero. The solution dY becomes:

$$dY = \frac{1}{\Delta} \cdot \{dG\} \tag{10a}$$

which is unambiguously positive. This implies that in the absence of a wealth effect in the consumption function there is no direct impact on income resulting from the financing of government expenditures. This result certainly contradicts both recent Monetarist discussions (see, for example, Karl Brunner and Allan Meltzer, p. 953; Milton Friedman, p. 51; and John Culbertson, p. 463) of and recent attempts to model (see articles by Silber and Meyer) the crowding-out effect in which crowding out occurs independently of any wealth effect in the consumption function. While Hansen has offered an additional channel through which crowding out can occur, namely through the wealth effect in the consumption function, he has in the process omitted the channel most frequently emphasized by Monetarists: the direct impact of an increase in the supply of government bonds on interest rates in private credit markets.

II. The Crowding Out of Private Borrowers

A major argument of the Monetarists is the failure of income expenditure models to explicitly consider the impact on credit markets resulting from the financing of a government deficit. The design of Hansen's model is intended to capture the impact of the financing of government deficits on the private credit market. Its specification of portfolio behavior, however, prevents it from doing so.

A bond financed fiscal operation can be described in terms of direct impacts and feedback responses.[2] Most macro models include a single direct effect: the *direct fiscal impact*, (*D1*)—the direct impact of an increase in G on aggregate demand by virtue of the fact that G is a component of aggregate demand. In such models, a bond financed fiscal policy is unambiguously expansionary unless one or more parameters take on extreme values (for example, zero interest elasticity of demand for money or infinite interest elasticity of investment). The only way crowding out can occur in such models is through the negative feedback response. As this response is activated by an increase in income, it can at best prevent income from changing; it can never generate a decline in income.

Recent contributions by Silber and Meyer have introduced two additional direct effects, both arising from the increase in the supply of government bonds: the *direct wealth impact*, (*D2*) and the *direct portfolio impact*, (*D3*). These effects were ignored in previous models either because of the failure to take into account the government budget constraint or because of specifications of the consumption and money demand functions that excluded any direct influence of changes in the government bond supply. The direct wealth impact is the increase in consumption induced by the increase in wealth associated with the increase in the supply of government bonds. The direct portfolio impact arises from the direct impact of an increase in government bonds on interest rates. An increase in the supply of government bonds generates excess supply in the bond market, driving up the interest rate. The increase in the interest rate reduces investment. The direct wealth impact is expansionary but the direct portfolio impact is restrictive. Therefore, the net effect of a bond financed fiscal operation is ambiguous. Complete crowding out can occur without any parameters taking on extreme values and a bond financed increase in G may even result in a decline in income.

---

[1] An increase in the supply of government bonds increases consumption through the increase in disposable income (coupon payments) and through the increase in wealth (discounted value of current and future coupon payments). This appears to be double counting. To avoid this problem we eliminate the c_1dB terms in Hansen's multipliers.

[2] Direct impacts refer to the *initial* impact of the increase in government expenditures and increase in the supply of government bonds on aggregate demand and hence income. These initial impacts can be on consumption via changes in disposable income and/or wealth associated with the operation, on investment via changes in interest rates directly associated with the operation, or on government expenditures. Feedback responses arise in response to the initial changes in income. There are two major feedback responses: a positive feedback response on components of aggregate demand which are positive functions of income, and negative feedback effects due to the income induced rise in interest rates on components of aggregate demand that are negatively related to interest rates. In Hansen's multipliers, the parameters that govern the magnitude of the direct impacts appear in the multiplicand, and the parameters that govern the feedback responses appear in the basic multiplier, $1/\Delta$.

Hansen's model includes the direct fiscal and direct wealth impacts but excludes the direct portfolio impact on investment. Why then does he also get an ambiguous multiplier and how can his model, with its detailed treatment of both government and private financing of expenditures, fail to capture the direct impact of an increase in government bonds on the private bond rate? The ambiguous sign of his multiplier results from a fourth direct impact, excluded in previous models: *the direct interest-induced wealth impact on consumption,* ($D4$)—the impact on consumption of the decline in wealth due to the direct impact of the increase in government bond supply on the government bond rate. This effect is restrictive.

This is not, however, the channel emphasized by Monetarists. For example, note the mechanism emphasized by Culbertson:

> Fiscal policy provides additional spending in a world of sparse spending opportunities. But it does not provide a new source of finance in a world where spending is constrained by sources of finance. The government expenditures are financed in debt markets in competition with private expenditures. The case least favorable to fiscal policy is that in which the additional government borrowing simply crowds out an equal (or conceivably greater) volume of borrowing that would have financed private expenditures. [p. 463]

Hansen apparently believes he has captured the mechanism referred to by Culbertson: "Our model thus allows for the 'crowding-out' from the financial markets of private borrowers when the government finances a deficit by sales of securities" (p. 552, fn. 10). Yet if $c_2 = 0$ in Hansen's model,[3] the effect on income of a bond financed increase in G is unambiguously positive, in contrast with the direct quote above by Culbertson and the models of Silber and Meyer.[4]

Hansen's model fails to generate the direct portfolio impact on investment because the nonbank private sector holds money and government bonds and the banking system holds reserves and private bonds (loans), but no one holds both government and private bonds. An increase in the supply of bonds increases the government bond rate but does not put upward pressure on the private bond (loan) rate. Despite what appears to be the attractive feature of including both government and private bond markets, the failure to thoroughly interconnect the two markets prevents the model from capturing the crucial role of the credit market in the crowding-out effect. This defect, however, can be easily remedied.

III. Respecification of Hansen's Model

If we respecify the model to allow both households and commercial banks to hold government bonds, the government is forced to compete directly with the private sector for sources of finance. This competition, in turn, leads to the type of financial market crowding out the Monetarists have emphasized.

This respecification necessitates the following changes in Hansen's basic model (his equations (1)–(8) plus (9′), p. 553): Hansen's equation (6) is replaced by:

---

[3] Whenever we set $c_2 = 0$ we assume the marginal propensity to consume out of interest payments is also zero. We acknowledge that Hansen has captured all the wealth effects generated by a bond financed fiscal policy. We set $c_2 = 0$ so we can concentrate on other effects he has omitted.

[4] Note further that if we set $c_2 = 0$ the multiplier for the financing of an initial deficit D_0 by issuing new bonds is

$$dY = \{(D_0 + dB)(\delta_3) - dB/r_g(\delta_3)\}$$

where δ_3 is positive. The increase in the supply of bonds must equal the coupon payments on the new bonds (dB) as well as the initial deficit. Therefore $dB/r_g = D_0 + dB$ and $dY = 0$.

$$(6') \quad \alpha M^b = m_1(r_g - \mu r_b) + m_2 Y + m_3 Bp/r_g$$

where Bp = the number of government bonds held by the household sector.

Hansen's equation (7) is replaced by:

$$(7') \quad \bar{K} + I = (\alpha - 1)M^b - Bc/r + L^b$$

where Bc = the number of government bonds held by commercial banks. This relation still assumes that all private investment is financed through bank loans, but as commercial banks are now allowed to hold government securities any bonds held by commercial banks reduce the availability of funds to the business sector.

Two new equations are required to complete the model:

$$(11) \quad Bc/r_g = e_1(r_g - r_b) + e_2$$

$$(12) \quad B = Bc + Bp$$

Equation (11) specifies the commercial banks' demand for government bonds as a positive function of the difference between the government bond and bank loan rates. Equation (12) requires that the holdings of government bonds by households and commercial banks sum to the total stock outstanding.

Finally, we assume there is no wealth effect in the consumption function and equation (2) is replaced by:

$$(2') \quad C = c_1(Y - T) + c_3$$

Letting all policy instruments, other than dG and dB, and all autonomous changes go to zero, we solve for the effect of a bond financed increase in government expenditures on income:

$$(13) \quad dY = \frac{1}{\Delta''}\{dG - [dB/r_g](\pi_3)\}$$

The basic multiplier $1/\Delta''$ is assumed to be positive and

$$\pi_3 = i_1 e_1 m_3 \div [m_4(\alpha\beta_1 - i_1 + e_1) + e_1(m_3 i_1 - \alpha\beta_1 m_3 - m_1\mu - \alpha\beta_1)] > 0$$

assuming $1 > \mu > 0$; i.e., banks' loan rate exceeds their deposit rate.

The two terms in the bracketed expression of equation (13) measure the impact of the bond financed operation. The first term, dG, is the direct fiscal impact; it is positive. The second term, $-(dB/r_g)(\pi_3)$, captures the direct portfolio impact on investment of the bond financing; it is negative. The increase in the supply of government bonds now puts upward pressure on both r_g and r_b which in turn puts downward pressure on, and crowds out, private investment. This crowding out of private investment is captured by the coefficient i_1 in π_3.[5]

There are, of course, other ways the model could have been specified so as to yield similar results. The portfolio behavior of firms could be altered by letting them, rather than commercial banks, hold government bonds in their portfolios. The effect of this modification would be to introduce the government bond rate, a measure of the opportunity cost of purchasing additional capital, as an argument in the investment function. Any change in the government bond rate would then have a direct impact on investment. Alternatively, we could have assumed firms finance all investment expenditures exclusively through the issue of private bonds to households. Households who now hold private as well as government bonds would provide the competitive link between the financing of private investment and the financing of government expenditures.[6]

---

[5] Note, further, that the multiplier for the financing of an initial deficit by issuing new bonds is now

$$dY = \frac{1}{\Delta''}\{-dB/r_g(\pi_3)\}$$

which is unambiguously negative under the assumption that $c_2 = 0$. Recall that this expression for dY would be zero in Hansen's model if $c_2 = 0$.

[6] It is interesting to note, however, that in the latter case the direct portfolio impact on investment is no longer unambiguously restrictive. The increase in the supply of government bonds will have two effects: 1) there will be a reduction in the demand for private bonds due to the increase in the government bond rate (substitution effect), but 2) there will be an increase in the demand for private bonds due to the increase in wealth associated with the increase in the supply of government bonds (wealth effect). The former impact puts upward pressure on the private bond rate while the latter impact puts downward pressure on this rate. The net impact on the private bond rate, and hence investment, is ambiguous.

IV. Bond Financed Fiscal Policy in the *U.S.* Model

Hansen points out that "It is immediately clear that what can be done under one of these budget constraints can also be done under the other . . . " (p. 550). A bond financed increase in government expenditures should yield identical results under the two regimes. However, the multiplier for such an operation while ambiguous in the European model (see equation (10) above) is unambiguously positive in the *U.S.* model! The multiplier in the *U.S.* model is

$$dY = \frac{1}{\Delta}\{(1 + \delta_3')dG\} \tag{14}$$

Hansen claims that δ_3' is unambiguously positive so that $dY/dG > 0$. This result, if correct, implies that the specific form of the budget constraint might be an important issue in the controversy between Keynesians and Monetarists. The contradiction, however, is erroneous, arising from Hansen's misreading the sign of the δ_3' term in (14). The full expression for δ_3' is:

$$\delta_3' = (c_2 B/r_g^2)\frac{m_3}{m_4(1 - r_g)} + \frac{c_1 r_g + c_2}{1 - r_g} \tag{15}$$

The first term on the right is negative ($c_2 > 0$, $m_3 > 0$, but $m_4 < 0$) and the second term is positive. The δ_3' term includes the two wealth effects (and the additional impact via the coupon payments) associated with an increase in the supply of government bonds: the first term is the restrictive impact of a higher government bond rate on consumption via the interest-induced wealth effect, and the second term is the positive wealth effect due to the increase in the number of government bonds at the initial interest rate. The multiplier, of course, still is missing the direct portfolio impact on investment.

V. Conclusion

Hansen's paper includes two interesting innovations: the requirement that all investment be financed through bank loans and the limitation on policy options imposed by institutional arrangements. Hansen fails to exploit the former and reports incorrect results concerning the implications of the latter. Readers may, therefore, have failed to appreciate the value of Hansen's innovations. We hope our comments help to exploit Hansen's innovations and contribute toward completing the taxonomy he began.

Default Risk, Scale, and the Homemade Leverage Theorem: Note

By PAO LUN CHENG*

In a recent article in this *Review*, Vernon Smith presented three theorems of considerable significance concerning scale, leverage, default risk, and expected utility of investor's final wealth contingencies. The theorems are derived from a model in which there is a single corporation[1] and a number of investors not necessarily having identical utility functions of wealth. The corporation makes all financial decisions at the beginning of a single interval of real investment. At the end of the period, in accordance with the contractual claim conditions of securities, it distributes a stochastic cash flow X among investors not necessarily having identical subjective distributions of X. Smith restricted himself to dealing with one class of debt whose claim on X is strictly prior to that of a single class of common shares. In addition to these two assets, each investor can hold a third asset, cash, with zero certain return. He showed that an investor's expected utility depends on the financial aggregates Y, Z, and M, where Y and Z are respectively the equilibrium market value of shares and bonds and $M=Y+Z$ is the scale of investment by the firm to generate X. Smith emphasized the fact that Y, Z, M, and $\mu=Z/Y$, the market leverage, represent externalities to the firm as well as to the investors. His theorems have to do with the effect of a change in the market leverage on an investor's expected utility.

With respect to Theorems 1 and 2, Smith disallowed the existence of a loan market for personal borrowing and lending, as compared with the models, for example, of Franco Modigliani and Merton Miller, Jan Mossin, John Lintner, and others, who assumed unrationed borrowing by investors at a riskless rate. For Theorem 3, however, Smith permitted the investors to borrow on personal account to buy shares without rationing at a rate which may be greater than, equal to, or less than the nominal lending rate on corporate bonds. Finally, for Theorems 2 and 3, the assumption of stochastic constant returns to scale is made, i.e., the investors' expected utilities are independent of M.

In an earlier paper, Smith (1970) expounded a Fundamental Leverage Theorem, which is essentially his Theorem 2. A comment by Uri Ben-Zion and Michael Balch on the theorem showed that it cannot hold if a change in the market leverage μ affects the nominal corporate bond rate $R-1$. Unfortunately, Ben-Zion and Balch, p. 293, fn. 3, were unable to provide the crucial proof of the intuitively appealing proposition that $dR/d\mu>0$ under the condition of positive default risk. The purpose of this comment is to show that $dR/d\mu>0$ when $Pr(X<X^*)>0$, where X^* is the firm's minimum cash flow required to escape default. If $dR/d\mu>0$, Smith's Theorems 2 and 3 will not hold, but his Theorem 1 stands, since the latter theorem assumes no default risk, i.e., $dR/d\mu=0$. In order to demonstrate the importance of the sign of $dR/d\mu$ to his theorems, we begin with his equation (noted as (6) in his text), the expected utility of an investor's final wealth.

$$(1)\qquad V=\int_{-\infty}^{0}U(x)H(M,X)dX+\int_{0}^{X^*}U(W')H(M,X)dX+\int_{X^*}^{\infty}U(W'')H(M,X)dX$$

---

[1] Later in the article Smith generalized Theorem 2 for the case of two corporations.

where

$H(M, X)$ = the investor's subjective probability distribution of X, associated with a scale M
$W' = X(z/Z)+x$
$= [(1+\mu)zX/\mu M]+x$, his final wealth if $0<X\leq ZR$
$W'' = zR+(X-ZR)(y/Y)+x$
$= zR+[1+\mu)yX/M]-\mu Ry+x$, his final wealth if $ZR<X$
Z, Y = market values of bonds and shares, respectively
x, y, z = his cash holdings, market value of share holdings, and market value of bond holdings, respectively
$X^* = ZR$, the firm's contractual obligations to bondholders
$R = X^*/Z$, one plus the contractual or nominal rate of interest on debt Z

With the way V, W', and W'' are specified, it is obvious both R and X^* affect V as well. Moreover, although Smith cogently argued that Z and Y are externalities, he seemed to assume implicitly that the nominal rate $R-1$ can be selected by the firm such that the market value of bonds Z will equal the face value of bonds, with the result that ZR represents the total payments to bondholders if the firm escapes default. But Z is an externality and one cannot expect the firm to select R such that $ZR=X^*$. Thus, a reasonable way to interpret Smith's specifications in this regard is to treat X^* as the total face value of bond certificates bearing *no* coupon interest, or equivalently, X^* is the number of discount bonds each having a face value of one dollar, entitling the holder of one bond to one dollar at the end of the period if the firm escapes default. We can then let Z be the market value of X^* to be determined as an externality and treat $R=X^*/Z$ as one plus the nominal market bond yield for the period. It is to be recognized that R represents a function of the internal decision variable X^* of the firm as well as the external market variable Z. We shall show that Z, Y, μ, and R depend on X^* and $dR/d\mu>0$ if the default risk is positive, after which the effect of $dR/d\mu>0$ on Smith's theorems will then be discussed in full.

Let the random variables Q and G denote the total return to bondholders and shareholders, respectively:

$$(2)\qquad Q = \begin{cases} 0, & X \leq 0 \\ X, & 0 < X \leq X^* \\ X^*, & X^* < X \end{cases}$$

$$(3)\qquad G = \begin{cases} 0, & X \leq X^* \\ X - X^*, & X^* < X \end{cases}$$

Although the investors may differ with respect to their subjective distributions of X, and hence, Q and G, they must obviously all agree that $Q+G=X$. Note that Q and G are conditional upon the choice of X^* by the corporation.

Suppose, instead of X^*, the firm chooses to issue X' discount bonds, $X'>X^*$. We have, instead:

$$(4)\qquad Q' = \begin{cases} 0, & X \leq 0 \\ X, & 0 < X \leq X' \\ X', & X' < X \end{cases}$$

$$(5)\qquad G' = \begin{cases} 0, & X \leq X' \\ X - X', & X' < X \end{cases}$$

As before, $Q'+G'=X$. Since there is no reason to expect a change in the investor's subjective distributions of X due to the change of X^* to X', each investor will notice that $F(Q')\leq F(Q)$ and $F(G')\geq F(G)$, where $F(\cdot)$ represent distribution functions. That is, for each investor, the condition of first-degree stochastic dominance exists[2] so that Q' is preferred to Q and G preferred to G'. The change in absolute preference in the same direction for every investor must imply that the equilibrium market values of Q' and G', say Z' and Y', must be such that $Z'/Y'>Z/Y$. Hence $\mu'>\mu$, implying $d\mu/dX^*>0$.

To reinforce our argument, in lieu of issuing a single class of X' discount bonds, the firm can choose to issue two classes of discount bonds plus shares: a first class of X^* discount bonds whose return is represented by the random variable Q, another class of $X'-X^*$ subordinate discount bonds whose return is represented by Q_1 where

---

[2] See Josef Hadar and William Russell, p. 27.

$$(6) \quad Q_1 = \begin{cases} 0, & X \leq 0 \\ 0, & 0 \leq X < X^* \\ X - X^*, & X^* \leq X < X' \\ X' - X^*, & X' \leq X \end{cases}$$

It is important to note that by referring to (2)–(6), $Q_1+G'=G$, $Q_1+Q=Q'$, and $Q+Q_1+G'=Q+G=Q'+G'=X$. In other words, if the firm chooses to issue a single class of X^* discount bonds, the return to shares G can be separated into Q_1 and G'. For example, suppose an investor i owns a fraction z_i/Z of X^* and a fraction y_i/Y of old shares with return G. The firm can "call in" all the old shares and replace them with $X'-X^*$ subordinate bonds with return Q_1 and new shares with return G', and remit to each investor i a fraction y_i/Y of subordinate bonds and new shares. Obviously, the investor's wealth contigency is unchanged, for $(y_i/Y)(Q_1+G')=(y_i/Y)G$. Note that the firm has succeeded in increasing its leverage, for $\Sigma_i(y_i/Y)\cdot(Q_1+G')+Q=Q_1+G'+Q=Q'+G'$. That is, the issuance of two classes of bonds is equivalent to the issuance of a single class of X' discount bonds.[3] Thus, with altogether three classes of securities with returns represented by Q, Q_1, and G', the equivalent of any two-class bonds and shares financing composition can be created. In the market, since $Q+Q_1=Q'$, the total value of X^* discount bonds and $X'-X^*$ subordinate bonds $Z+Z_1$ must be equal to the value of X' single class of bonds Z', i.e., $Z+Z_1=Z'$. By the same token, since $Q_1+G'=G$, the market value of G' must be $Y'=Y-(Z'-Z)=M-Z'$. It follows that

$$\mu' = \frac{Z'}{Y'} = \frac{Z'}{M - Z'} = \frac{Z + Z_1}{M - Z - Z_1}$$
$$= \frac{Z + Z_1}{Y - Z_1} > \mu = \frac{z}{y}$$

which is equivalent to $d\mu/dX^*>0$. Moreover, since $Z'=Z+Z_1$ so that $Z'>Z$, we can infer that $dZ/dX^*>0$. Similarly, since $Y=Y'+(Z'-Z)$ so that $Y>Y'$, whence $dY/dX'<0$.

In order to show $dR/d\mu>0$ when the default risk is positive, we need only to show $dR/dX^*>0$, since $d\mu/dX^*>0$ has already been established. Consider the case of X^* discount bonds and $X'-X^*$ subordinate bonds whose returns are represented by Q and Q_1, respectively. Let Q/X^* and $Q_1/(X'-X^*)$ be their respective returns per bond. Note that, using (2) and (6),

$$Q/X^* = \begin{cases} 0, & X < 0 \\ X/X^*, & 0 \leq X < X^* \\ 1, & X^* \leq X < X' \\ 1, & X' \leq X \end{cases}$$

$$Q_1/(X' - X^*) = \begin{cases} 0, & X < 0 \\ 0, & 0 \leq X < X^* \\ \dfrac{X - X^*}{X' - X^*}, & X^* \leq X < X' \\ 1, & X' \leq X \end{cases}$$

Again, $F(Q/X^*) \leq F(Q_1/(X'-X^*))$ so that Q/X^* stochastically dominates $Q_1/(X'-X^*)$. Hence, each investor absolutely prefers Q/X^* to $Q_1/(X'-X^*)$ so that the prices of bonds will be $Z/X^*>Z_1/(X'-X^*)$. Equivalently, we have

$$(7) \quad \frac{X^*}{Z} < \frac{X' - X^*}{Z_1}$$

suggesting a greater nominal rate of return for the subordinate bonds. Since the choice of issuing two classes of bonds with random returns Q and Q_1 is equivalent to the choice of issuing a single class of X' bonds with return Q', and $Z+Z_1=Z'$, the nominal return of Q' is

$$\frac{X'}{Z'} = \frac{X^* + (X' - X^*)}{Z + Z_1}$$

In conjunction with (7), we get

$$(8) \quad \frac{X^*}{Z} < \frac{X^* + (X' - X^*)}{Z + Z_1} < \frac{X' - X^*}{Z_1}$$

---

[3] If an equilibrium already exists before the new bond distribution, then the same equilibrium must exist after the new bond distribution. The existence of the prior equilibrium is implied by the comparative static analyses by Smith throughout his article.

Thus, the bond rate of a single class of X' discount bonds is greater than the rate of a single class of X^* discount bonds but is less than the rate of the subordinate bonds. It follows that $dR/dX^*>0$.

With $dR/d\mu>0$ established when the default risk is positive, we return to Smith's expected utility function (1) for an examination of his theorems. The investor selects (x^0, y^0, z^0) so as to maximize V subject to his initial wealth $W_0=x+y+z$, giving the Lagrangian $L=V+\lambda(W_0-x-y-z)$. The firm issues a single class of X^* discount bonds, plus shares. As before, Z and Y are the equilibrium market values of Q and G, respectively. Following Smith (p. 69), the Kuhn-Tucker conditions are

$$(9) \quad L_{x^0} \leq 0, \qquad x^0L_{x^0} = 0$$

$$(10) \quad L_{y^0} = I_1 + \mu I_2 - \lambda \leq 0, \qquad y^0L_{y^0} = 0$$

$$(11) \quad L_{z^0} = [(1+\mu)J_0/\mu] + J_1 - \lambda \leq 0, \qquad z^0L_{z^0} = 0$$

where

$$(12) \quad I_1 = \int_{X^*}^{\infty} U'(W'')(X/M)HdX$$

$$I_2 = \int_{X^*}^{\infty} U'(W'')[(X/M) - R]HdX$$

$$J_0 = \int_{0}^{X^*} U'(W')(X/M)HdX$$

$$J_1 = \int_{X^*}^{\infty} U'(W'')RHdX$$

Let us write the envelope equation

$$(13) \quad \frac{dV^0}{d\mu} = V^0_\mu + V^0_M\left(\frac{dM}{d\mu}\right) + V^0_R\left(\frac{dR}{d\mu}\right)$$

Smith's Theorem 1 states (p. 70):

> If there is no default risk on corporate bonds, an investor's optimal portfolio will be such that he will never prefer a decrease in the debt-equity ratio, and if $z^0>0$ he will be indifferent to a change in the debt-equity ratio, i.e.,

$$dV^0/d\mu = V^0_\mu + V^0_M(dM/d\mu) = 0$$

Having successfully demonstrated (p. 70) that $dM/d\mu=0$ when there is no default risk and since $dR/d\mu=0$, which is implicitly and correctly assumed in this case, (13) reduces to

$$dV^0/d\mu = V^0_\mu = -(z^0/\mu^2)J_0 + y^0I_2$$

By substituting from (9)–(12), he obtains

$$(1+\mu)V^0_\mu = -y^0L_{z^0} \geq 0, \qquad z^0L_{z^0} = 0$$

and Theorem 1 follows.

Let us now use (13) to examine his Theorem 2 (p. 71):

> If a corporation can invest at constant return to scale, and the default risk on its bonds is positive, then an investor's optimal portfolio will have the property that he will prefer the corporation to increase, leave unchanged or decrease its debt-equity ratio according as $\mu \gtreqless (z^0/y^0)$.

Since $V^0_M=0$ follows from the assumption of constant return to scale while retaining the implicit but incorrect assumption $dR/d\mu=0$ in this case of positive default risk, he continued to work with $dV^0/d\mu=V^0_M$. Substituting from (9)–(12), he obtained

$$dV^0/d\mu = V^0_\mu = (\lambda - J_1)(y^0 - z^0/\mu)/(1+\mu)$$

Using the inequality in (11) $\lambda-J_1\geq(1+\mu)J_0/\mu$, he reached the conclusion in Theorem 2. However evaluating (13) by dV^0/dX^* and then dividing the result by $d\mu/dX^*>0$, we obtain instead

$$(14) \quad dV^0/d\mu = (\lambda - J_1)(y^0 - z^0/\mu)/(1+\mu) + (z^0 - \mu y^0)\cdot\int_{X^*}^{\infty}(dR/d\mu)U'(W'')HdX$$

Note that the second term will have a sign always opposite to the sign of the first term, for as $(y^0-z^0/\mu)\gtreqless 0$, $(z^0-\mu y^0)\lesseqgtr 0$, while $dR/d\mu>0$ and $U'(W'')>0$. Consequently, Theorem 2 does not hold.

It is interesting to rewrite (14) as

$$(15) \quad dV^0/d\mu = (y^0 - z^0/\mu)\int_{X^*}^{\infty}\{(X/M) - R[1+(dR/R)/(d\mu/\mu)]\}U'(W'')HdX$$

using the fact that

$$(\lambda - J_1)/(1+\mu) = I_2 = \int_{X^*}^{\infty} U'(W'')[(X/M) - R]H\,dX$$

when $L_y^0=0$, $y^0>0$ so that $\lambda=J_1+(1+\mu)I_2$. It is clear that the sign of $dV^0/d\mu$ depends not only on the sign of (y^0-z^0/μ), but also on the magnitude of the "Leverage elasticity" of the nominal bond yield $(dR/R)/(d\mu/\mu)$. For example, if the elasticity is zero under the condition of zero default risk, (15) reduces to

$$\begin{aligned} dV^0/d\mu &= (y^0 - z^0/\mu)I_2 \\ &= -(z^0/\mu^2)J_0 + y^0 I_2 \\ &= y^0 I_2 \end{aligned}$$

where $J_0=0$ when bonds are riskless. Note that this is precisely the case for Smith's Theorem 1. However, when the elasticity is positive, or equivalently, $dR/d\mu>0$, the integral in (15) can be of any sign, depending on the choice of X^*. Therefore, we cannot a priori assert the direction of an investor's preference for leverage solely by comparing μ and z^0/y^0 as Theorem 2 would have us believe.

Let us now turn to Smith's Theorem 3 dealing with investors who are allowed to borrow to buy shares. Having borrowed an additional amount x to buy shares at a contractual rate $R'-1$, an investor after paying off his debt and interest will find his final wealth exactly zero if $(X-X^*)y/Y=xR'$. In other words, if $X=X_0\equiv(xR'+\mu Ry)Y/y$ the investor's final wealth is zero. Defining $\theta=(X/M)-1$, we see that the critical value of θ for the investor, corresponding to X_0, is

$$\theta' = [1/(1+\mu)][(x/y)R' + \mu R] - 1$$

Following from the definition of θ and θ', Smith characterized the investor's final wealth as follows:

$$W' = 0, \qquad \text{if } \theta \leq \theta'$$

$$W'' = (\theta+1)y + \mu(1+\theta-R)y - xR', \qquad \text{if } \theta > \theta'$$

The expected utility is simply

$$V = \int_{\theta'}^{\infty} U(W'')f(\theta)d\theta$$

with budget constraint $W^0=y-x$ and Lagrangian $L=V+\lambda(W_0+x-y)$.

Continuing the assumption of stochastic constant return to scale, Smith arrived at the conclusion by again taking for granted $dR/d\mu=0$:

$$V_\mu^0 = dV^0/d\mu = y^0 J(R'-R)/(1+\mu) \gtreqless 0 \quad \text{as } R'-R \gtreqless 0$$

$$\text{where } J = \int_{\theta'}^{\infty} U'(W'')f(\theta)d\theta > 0$$

Hence, his Theorem 3 (p. 72):

> Under stochastic constant returns to scale the investor whose optimal portfolio requires him to borrow on personal account to buy shares, and who is not rationed by his creditor, will prefer the corporation to increase, leave unchanged, or decrease its debt-equity ratio according as his personal borrowing rate is greater than, equal to, or less than the lending rate on corporate bonds.

But $dR/d\mu>0$. Instead, we obtain

$$\begin{aligned} (16) \quad dV^0/d\mu &= y^0 I_2 - y^0 J\mu(dR/d\mu) \\ &= y^0 J[(R'-R)/(1+\mu) - \mu(dR/d\mu)] \end{aligned}$$

upon substituting

$$\begin{aligned} I_2 &= \int_{\theta'}^{\infty} U'(W'')[(X/M) - R]f(\theta)d\theta \\ &= (\lambda - RJ)/(1+\mu) \end{aligned}$$

$$\text{and} \quad \lambda = R'J$$

From (16), we conclude $dV^0/d\mu \gtreqless 0$ according as $R'-R \gtreqless \mu(1+\mu)(dR/d\mu)$, which reduces to Theorem 3 if $dR/d\mu=0$. Since $dR/d\mu>0$, a margin investor's preference for μ depends a great deal on the current value of μ (and, of course X^*), which in turn affects R and $dR/d\mu$. For a given personal borrowing cost R', for example, an inequality $R'-R>\mu(1+\mu)(dR/d\mu)$ may be easily reversed as μ and R respond to an increase in X^*, provided that $dR/d\mu$ does not decrease sufficiently to offset the leverage effects.

NOTES

EIGHTY-EIGHTH ANNUAL MEETING OF THE AMERICAN ECONOMIC ASSOCIATION

Dallas, Texas, December 27–30, 1975

Preliminary Announcement of the Program

Saturday, December 27, 1975

10:00 A.M. EXECUTIVE COMMITTEE MEETING

Sunday, December 28, 1975

8:30 A.M. SAVINGS BEHAVIOR: NEW INFLUENCES AND CONSEQUENCES
Chairperson: ROBERT FERBER, University of Illinois
Papers: MARTIN FELDSTEIN, Harvard University
The Impact of Social Security
ALAN BLINDER, Princeton University
Wealth Distribution and Intertemporal Wealth Transfers
Discussants: FRANCO MODIGLIANI, Massachusetts Institute of Technology
ROBERT LAMPMAN, University of Wisconsin, Madison

8:30 A.M. UNCERTAINTY AND INCOMPLETE MARKETS*
Chairperson: DAVID CASS, University of Pennsylvania
Papers: MICHAEL ROTHSCHILD, Princeton University
Non-Optimizing Models of Administrative Behavior
HAYNE LELAND, University of California, Berkeley
Corporate Decision Making in Incomplete Markets
ROBERT FORSYTE, Carnegie-Mellon University
Efficiency in Incomplete Markets
JAMES JORDON, University of Pennsylvania
The Predictability of Prices in a Monetary Economy
Discussants: (To be announced)

8:30 A.M. ECONOMIC JUSTICE THROUGH REDISTRIBUTION: REALITY OR MYTH?* (Joint Session with the Association for the Study of the Grants Economy)
Chairperson: JULIUS REZLER, Loyola University, Chicago
Papers: TAPAN MUNROE, University of the Pacific and Massachusetts Institute of Technology, AND THEODORE TSUKAHARA, Pomona College
The Grants Economy and Contemporary Theories of Distributive Justice
SAMUEL M. LOESCHER, Indiana University
The Economics of Love and the Price System
C. LOWELL HARRISS, Columbia University
Corporate Giving: the Directions of Redistribution
RICHARD F. DYE, University of Michigan
Estimating Demand Equations for Charitable Giving
Discussants: JULIUS MARGOLIS, University of Pennsylvania
FREDERICK L. PRYOR, Swarthmore College
HOWARD P. TUCKMAN, Florida State University

8:30 A.M. FINANCE AND INDUSTRIAL ORGANIZATION* (Joint Session with the American Finance Association)
Chairperson: (To be announced)
Papers: CLEMENT G. KROUSE, University of California, Los Angeles
Capital Market and Allocative Efficiency with Technological Uncertainty
GERSHON MANDELKER, Carnegie-Mellon University
An Empirical Analysis of the Gains from Mergers
JAMES ELLERT, Queen's University
Antitrust Enforcement and the Behavior of Stock Prices

---

* Not to appear in *Papers and Proceedings*

Discussants: JOHN LONG, University of Rochester
J. FRED WESTON, University of California, Los Angeles
(Others to be announced)

10:30 A.M. CURRENT ISSUES IN METHODOLOGY*
Chairperson: RICHARD M. CYERT, Carnegie-Mellon University
Papers: LEWIS E. HILL AND GENE USELTON, Texas Tech University
Ludwig von Mises' Epistemology: A Critical Evaluation
EUGENE ROTWEIN, Queens College of the City University of New York
A Survey of the Methodological Discussion of the Last Few Decades
STEPHEN T. WORLAND, Notre Dame University
Methodological Problems of Welfare Economics: A Reflective View
Discussants: MARTIN BRONFENBRENNER, Duke University
EMILE GRUNBERG, University of Akron

10:30 A.M. THE PRICING OF OPTIONS* (Joint Session with the American Finance Association)
Chairperson: FISCHER BLACK, Massachusetts Institute of Technology
Papers: ROBERT MERTON, Massachusetts Institute of Technology
Option Pricing for Noncontinuous Stock Price Movements
JOHN COX, Stanford University
The Valuation of Financial Claims
MYRON S. SCHOLES, University of Chicago
Taxes and the Pricing of Options
HENRY LATANÉ AND RICHARD RANDLEMAN, University of North Carolina
Implied Versus Actual Standard Deviations of Daily Stock Price Ratios
Discussant: STEPHEN ROSS, University of Pennsylvania

10:30 A.M. IS THERE A CAPITAL SHORTAGE?* (Joint Session with the American Finance Association)
Chairperson: ERNEST T. BAUGHMAN, Federal Reserve Bank of Dallas
Papers: LEONALL ANDERSEN, Federal Reserve Bank of St. Louis
Capital Shortage? Theory and Empirical Evidence
ANDREW F. BRIMMER, Harvard University
Capital Markets and Competition for Long-Term Funds
ROBERT LINDSAY, New York University
Capital Shortages—Sectoral and Global
Discussants: BENJAMIN FRIEDMAN, Harvard University
SALLY RONK, U.S. Treasury Department
CHARLES UPTON, University of Chicago

10:30 A.M. NEW DEVELOPMENTS IN THE THEORY OF MONOPOLISTIC COMPETITION
Chairperson: (To be announced)
Papers: GERALD BUTTERS, Princeton University
Survey of Advertising and Market Structures
MICHAEL PORTER, Harvard University
Market Structure and Performance
MICHAEL SPENCE, Stanford University
Monopolistic Competition

10:30 A.M. THE INTERNATIONAL MONETARY MECHANISM: RECENT PROBLEMS AND EVIDENCE
Chairperson: HOLLIS CHENERY, International Bank for Reconstruction and Development
Papers: JÜRG NIEHANS, Johns Hopkins University
Current Problems with the International Monetary Mechanism
JAGDISH BHAGWATI, Massachusetts Institute of Technology
The Less Developed Countries and International Monetary Mechanism
STEPHEN MAGEE, University of Chicago
Empirical Evidence on the International Economic System
Discussants: HOSSEIN ASKARI, University of Texas at Austin
POLLY REYNOLDS ALLEN, Princeton University

---

* Not to appear in *Papers and Proceedings*

10:30 A.M. STATE AND LOCAL PUBLIC FINANCE (Joint Session with Public Choice Society and Econometric Society)
Chairperson: WILLIAM S. VICKREY, Columbia University
Papers: RICHARD E. WAGNER, Virginia Polytechnic and State University
Institutional Constraints and Local Community Formation
EITAN BERGLAS, University of Rochester and Tel-Aviv University
On the Theory of Clubs
WILLIAM C. WHEATON, Massachusetts Institute of Technology
Alternate Institution for Collective Choice Making
Discussants: RONALD E. GRIESON, Columbia University
PETER B. MIESZKOWSKI, Houston University

10:30 A.M. NATIONAL FOOD POLICY FOR AN INTERDEPENDENT AND UNCERTAIN WORLD* (Joint Session with American Agricultural Economics Association)
Chairperson: LUTHER TWEETEN, Oklahoma State University
Papers: HENDRICK S. HOUTHAKKER, Harvard University
Do Consumers or the Nation Need a National Food Policy?
GARY L. SEEVERS, Council of Economic Advisors
Impact of Policy Alternatives on the Food Sector and Its Performance
Discussants: DARYLL E. RAY, Oklahoma State University
HOWARD W. HJORT, Schnittker Associates, Washington, D.C.

10:30 A.M. APPLICATION OF OPTIMAL CONTROL TO PROBLEMS OF ECONOMIC STABILIZATION (Joint Session with the Econometric Society)
Chairperson: JAMES S. DUESENBERRY, Harvard University
Papers: GREGORY C. CHOW, Princeton University
Control Methods for Macroeconomic Policy Analysis
ALBERT ANDO, University of Pennsylvania, AND CARL PALASH, Federal Reserve Bank of New York
An Econometric Analysis of Stabilization Policies: A Use of an Optimal Control Program
JOHN H. KALCHBRENNER AND PETER A. TINSLEY, Board of Governors of the Federal Reserve System
On the Use of Optimal Control Concepts in the Design of Aggregate Monetary Policies
Discussants: HENRY C. WALLICH, Board of Governors of the Federal Reserve System
GARY FROMM, National Bureau of Economic Research

12:30 P.M. JOINT LUNCHEON (With the American Finance Association)
Chairperson: FRANCO MODIGLIANI, Massachusetts Institute of Technology
Speaker: GUIDO CARLI, Governor, Bank of Italy

2:00 P.M. INDEXATION—MONETARY CORRECTION? (Joint Session with Econometric Society and the American Finance Association)
Chairperson: STANLEY FISCHER, Massachusetts Institute of Technology
Papers: DAVID LEVHARI AND NISSAN LIVIATAN, Hebrew University
Risk and Theory of Indexed Bonds
WILLIAM POOLE, Brown University
Indexing and the Capital Markets
HENRY AARON, The Brookings Institution
Indexation of the Tax System
Discussants: FISCHER BLACK, Massachusetts Institute of Technology
KAREN JOHNSON, Stanford University
JOHN BOSSONS, University of Toronto

2:00 P.M. INCENTIVES UNDER SOCIALISM: MODELS AND REALITY*
Chairperson: ZBIGNIEW M. FALLENBUCHL, University of Windsor
Papers: LEONID HURWICZ, University OF Minnesota
Incentives and Efficiency in Economic Decisions
ARON KATSENELINBOIGEN AND HERBERT S. LEVINE, University of Pennsylvania
Incentive Mechanisms in the Soviet Economy
C. ROBERT ROLL, The RAND Corporation
Incentives and Motivation in China
Discussants: EGON NEUBERGER, State University of New York at Stony Brook
FREDERIC M. SCHERER, Federal Trade Commission
ROBERT F. DERNBERGER, University of Michigan

---

* Not to appear in *Papers and Proceedings*

2:00 P.M. GRANTS IN MONETARY POLICY AND THE STRUCTURE OF THE FINANCIAL SYSTEM* (Joint Session with the Association for the Study of the Grants Economy)
Chairperson: ANDREW F. BRIMMER, Harvard University
Papers: GEORGE M. VON FURSTENBERG, Council of Economic Advisors
An Analytical Framework for Identifying Subsidy Components in Government Sponsored Credit
RICHARD COHN, Massachusetts Institute of Technology
The Implications for Mortgage Lenders of Removing Deposit Rate Ceilings
PATRIC H. HENDERSCHOTT, Purdue University
Grant Elements in the Operation of Federally Sponsored Credit Agencies in the Mortgage Market
THOMAS F. WILSON, Butler University
Identification and Measurement of Grant Elements in Monetary Policy
Discussants: JOSEPH SCHERER, Federal Reserve Bank of New York
THOMAS HAVRILESKY, Duke University

2:00 P.M. EXPERIMENTAL ECONOMICS
Chairperson: MARTIN SHUBIK, Yale University
Papers: JAMES FRIEDMAN, University of Rochester, AND AUSTIN HOGGATT, University of California, Berkeley
Pricing Signalling in Experimental Oligopoly
ROGER NOLL, California Institute of Technology
On the Pricing of Public Goods: Public Television Programming
VERNON L. SMITH, University of Arizona
Experimental Economics: Some Theories and Results
Discussants: CHARLES PLOTT, California Institute of Technology
MICHAEL ROTHSCHILD, Princeton University

2:00 P.M. MARXIST PERSPECTIVES ON THE CAPITALIST MACROECONOMY
Chairperson: LEONARD A. RAPPING, University of Massachusetts
Papers: JENS CHRISTIANSEN, Stanford University
Marx and the Falling Rate of Profit
JAMES CROTTY, University of Massachusetts, AND RAYFORD BODDY, American University
Capitalism, Instability, and Economic Policy
ARTHUR MACEWAN, Harvard University
World Capitalism and U.S. Economic Instability
Discussants: GEORGE FEIWEL, University of Tennessee
DONALD J. HARRIS, University of West Indies

2:00 P.M. NEW DEVELOPMENTS IN LABOR MARKET DYNAMICS (Joint Session with Econometric Society and Industrial Relations Research Association)
Chairperson: EDWARD KALACHEK, Washington University
Papers: CHARLES C. HOLT, RALPH E. SMITH, RICHARD S. TOIKKA, AND WILLIAM J. SCANLON, The Urban Institute
A Simulation Model of the Demographic Composition of Employment, Unemployment and Labor Force Participation
ROBERT J. FLANAGAN, Stanford University
The Economics of Racial Unemployment Differentials
ROBERT HALL AND RICHARD KASTEN, Massachusetts Institute of Technology
Labor Mobility and Occupational Success of Young Men
Discussants: FRANK BRECHLING, Northwestern University
CLIFFORD REID, Grinnell College
EMILY ANDREWS, U.S. Department of Labor–ASPER

2:00 P.M. ECONOMIC FLUCTUATIONS AND STABILIZATION POLICY, 1965–75: SOME ECONOMETRIC EVIDENCE*
Chairperson: LAWRENCE R. KLEIN, University of Pennsylvania
Papers: ALBERT A. HIRSCH, U.S. Department of Commerce
Econometric Review of Alternative Fiscal and Monetary Policies 1965–75—I
HAROLD SHAPIRO, University of Michigan
Econometric Review of Alternative Fiscal and Monetary Policies 1965–75—II
KEITH JOHNSON, Columbia University
Econometric Review of Alternative Fiscal and Monetary Policies, International Aspects—I

* Not to appear in *Papers and Proceedings*

Discussants: HENRY C. WALLICH, Board of Governors of the Federal Reserve System
WILLIAM FELLNER, American Enterprise Institute
R. JEFFREY GREEN, Council of Economic Advisers
GEORGE D. N. WORSWICK, National Institute of Economic and Social Research

2:00 P.M. POLITICAL ECONOMY: SOME USES OF THE EXIT-VOICE APPROACH
Chairperson: JAMES TOBIN, Yale University
Papers: RICHARD B. FREEMAN, Harvard University
Individual Mobility and Collective Action in the Labor Market
OLIVER E. WILLIAMSON, University of Pennsylvania
The Economics of Internal Organizations: Exit and Voice in Relation to Markets and Hierarchies
DENNIS R. YOUNG, State University of New York at Stony Brook
Consolidation or Diversity: Choices in the Structure of Urban Governance
Discussants: ALBERT O. HIRSCHMAN, Institute for Advanced Study
RICHARD R. NELSON, Yale University

8:00 P.M. RICHARD T. ELY LECTURE
Chairperson: JAMES TOBIN, Yale University
Speaker: ASSAR LINDBECK, Institute for International Economic Studies
Stabilization Policy in Open Economies with Endogenous Politicians

Monday, December 29, 1975

8:30 A.M. ENVIRONMENTAL ECONOMICS* (Joint Session with the American Association of Environmental Economists)
Chairperson: RALPH C. D'ARGE, University of Wyoming, AND ROBERT DORFMAN, Harvard University
Papers: WILLIAM J. BAUMOL, Princeton University
Environmental Economics in Perspective
A. NICHOLS AND RICHARD ZECKHAUSER, Harvard University
Should the Federal Government Stockpile Resources?
CLIFFORD RUSSELL AND WALTER SPOFFORD, Resources for the Future, Inc.
A Regional Environmental Management Model: Some Results
M. L. CROPPER, University of California, Riverside
Regulating Activities with Catastrophic Environmental Effects
Discussants: (To be announced)

8:30 A.M. ECONOMIC ISSUES IN IMPOSING MULTIPLE OBJECTIVES IN THE TRANSPORT-UTILITY SECTOR* (Joint Session with the Transportation and Public Utilities Group)
Chairperson: WILLIAM H. DODGE, University of Wisconsin
Papers: ROBERT W. HARBESON, University of Illinois
Social Welfare and Economic Efficiency in Transport Policy
TILLO E. KUHN, York University
Economies and Multiple Objectives in Urban Transportation
HARRY M. TREBING, Michigan State University
Broadening the Objectives of Public Utility Regulation
Discussant: JOEL DIRLAM, University of Rhode Island

8:30 A.M. SELECTION AND DIRECTION OF JOURNAL MATERIAL WITH REGARD TO CAREER DEVELOPMENT*
Chairperson: MARK PERLMAN, University of Pittsburgh
Papers: WILLIAM BRAINARD, Yale University
Some Results of the American Economic Association Readership Survey
HUGH NORTON, University of South Carolina
Equity and Effectiveness of the Editing Process as Perceived by the Producers of Manuscripts
ALICE VANDERMEULEN, University of California, Los Angeles
The Publication Problem as Viewed by an Erstwhile Editor
ROBERT EAGLY, Federal Reserve Bank of New York
Measuring the Scholarly Effectiveness of Journal Articles
Discussants: CHARLES WILSON, University of California, Los Angeles
MICHAEL LOVELL, Wesleyan University
DAVID A. KATZ, University of Missouri, Rolla

---

* Not to appear in *Papers and Proceedings*

8:30 A.M. IMPROVING THE DATA BASE FOR THE U.S. NATIONAL INCOME AND PRODUCT ACCOUNTS* (Joint Session with the Econometric Society)
Chairperson: David T. Hulett, Statistical Policy Division, Office of Management and Budget
Panelists: ROSANNE E. COLE, International Business Machines
ROBERT J. GORDON, Northwestern University
DALE W. JORGENSEN, Harvard University
DANIEL CREAMER, Consultant to the Conference Board and Chairman of GNP Data Improvement Project
EDWARD DENISON, The Brookings Institution

8:30 A.M. INFLATION AND STRUCTURAL ADJUSTMENTS IN THE RESIDENTIAL MORTGAGE MARKET* (Joint Session with the American Finance Association and American Real Estate and Urban Economics Association)
Chairperson: JACK GUTTENTAG, University of Pennsylvania
Papers: RICHARD COHN AND DONALD LESSARD, Massachusetts Institute of Technology
Recent Research on Indexation and the Housing Market
DONALD TUCKER, Board of Governors, Federal Reserve System
Indexation and the Housing Market
STANLEY S. STANSELL AND JAMES MILLER, Farm Credit Association
Study of Variable Rate Farm Credit Residential Mortgages
Discussants: ROBERT EDELSTEIN, University of Pennsylvania
RICHARD V. EASTIN, University of Southern California
ALAN DONZIGER, Villanova University

10:30 A.M. RECENT DEVELOPMENTS IN THE APPLICATION TO ECONOMICS OF DIFFERENTIAL TOPOLOGY AND GLOBAL ANALYSIS (Joint Session with Econometric Society)
Chairperson: TRUMAN BEWLEY, Harvard University
Papers: GERARD DEBREU, University of California, Berkeley
Regular Differentiable Economies
STEPHEN SMALE, University of California, Berkeley
Global Analysis and Dynamics in Equilibrium Theory
Discussants: DONALD BROWN, Yale University
HAL VARIAN, Massachusetts Institute of Technology

10:30 A.M. INFORMATION AND MARKET STRUCTURE (Joint Session with the Econometric Society)
Chairperson: VERNON L. SMITH, University of Arizona
Papers: STEVEN SALOP, Federal Reserve Board
Information and Industrial Organization
JOSEPH E. STIGLITZ, Stanford University
Information, and Capital Market: A Survey
JOHN RILEY, University of California, Los Angeles
Information, Screening, and Human Capital
Discussants: PAUL COOTNER, Stanford University
ELIZABETH E. BAILEY, Bell Laboratories and New York University
DALE MORTENSEN, Northwestern University

10:30 A.M. INTERGENERATIONAL TRANSFERS OF INEQUALITY (Joint Session with the Econometric Society)
Chairperson: ORLEY ASHENFELTER, Princeton University
Papers: MARY CORCORAN, Michigan State University, AND CHRISTOPHER JENCKS, Harvard University
The Effects of Family Background on Income: A Review and Some New Evidence
JERE BEHRMAN AND PAUL TAUBMAN, University of Pennsylvania
Intergenerational Transfers of Earnings and Occupational Status: The Contributions of Genetics and Environment
GLEN LAURI, Massachusetts Institute of Technology
Equal Employment Opportunity and Racial Income Differences
Discussants: RICHARD B. FREEMAN, Harvard University
MICHAEL L. WACHTER, University of Pennsylvania
FINIS WELCH, University of California, Los Angeles

---

* Not to appear in *Papers and Proceedings*

10:30 A.M. NEW DEVELOPMENTS IN PUBLIC FINANCE (Joint Session with the Econometric Society)
Chairperson: MARTIN FELDSTEIN, Harvard University
Papers: DAVID BRADFORD, Princeton University
Optimal Taxation
MICHAEL BOSKIN, Stanford University
Recent Econometric Research on Taxation
Discussants: EYTAN SHESHINSKI, Hebrew University
GEORGE BREAK, University of California, Berkeley

10:30 A.M. RISK BENEFIT ANALYSIS OF ALTERNATIVE ENERGY SOURCES*
Chairperson: ALAN S. MANNE, Harvard University
Papers: LESTER LAVE, Carnegie-Mellon University
Coal or Nuclear: The External Costs of Electricity Generation
THOMAS COCHRAN, Natural Resources Defense Council, Inc.
Risk Benefit Analysis in Nuclear Decisions
SAUL LEVINE, Nuclear Regulatory Commission
Overview of Nuclear Power Plant Risk Assessment
Discussants: (To be announced)

10:30 A.M. INCOME DISTRIBUTION IN DEVELOPING COUNTRIES (Joint Session with the Association for Comparative Economic Studies)
Chairperson: PAUL ROSENSTEIN-RODAN, Boston University
Papers: IRMA ADELMAN, University of Maryland, AND SHERMAN ROBINSON, Princeton University
Income Distribution and Structural Change in Developing Countries
MONTEK AHLUWAHLIA, International Bank for Reconstruction and Development
Income Distribution and Economic Development: Some Stylized Facts
MICHAEL BEST, University of Massachusetts
Uneven Development and Dependent Market Economies
Discussants: WILLIAM R. CLINE, The Brookings Institution
LANCE TAYLOR, Massachusetts Institute of Technology
ALEX O. WILLIAMS, University of Pittsburgh

10:30 A.M. CURRENT ISSUES IN THE FINANCING OF DEVELOPMENT*
Chairperson: ISAIAH FRANK, Johns Hopkins University
Papers: RAYMOND F. MIKESELL, University of Oregon
External Finance and the Current Resource Transfer Theory
JORGE RUIZ-LARA AND NICHOLAS BRUCK, Inter-American Development Bank
Development Finance Requirements at Different Stages of Development
WOUTER TIMS AND JO W. SAXE, International Bank for Reconstruction and Development
The Role of Petro-Dollars and Euro-Currencies in Development Finance
Discussants: HOSSEIN ASKARI, University of Texas at Austin
LESTER GORDON, Harvard Institute for International Development
ALBERT O. HIRSCHMAN, Institute for Advanced Study, Princeton University

2:00 P.M. TREND AND ANALYSIS IN BLACK ECONOMIC DEVELOPMENT (Joint Session with the National Economic Association)
Chairperson: ALFRED L. EDWARDS, University of Michigan
Papers: WILLIAM D. BRADFORD, Stanford University, AND ALFRED OSBORNE, University of California, Los Angeles
A Theoretical Investigation of the Entrepreneurship Decision in the Context of Black Economic Development
WALTER W. MCMAHON, University of Illinois
Influences on Investment by Blacks in Higher Education
KARL D. GREGORY, Oakland University, AND FLOYD HOGAN, Black Economic Research Center, New York
Recent Trends in the Development of Minority-Owned and Operated Businesses
KENNETH KNIGHT, University of Texas at Austin
Capital Problems in Minority Business Development
Discussants: ERIC SCHENKER, University of Wisconsin at Milwaukee
VINCENT R. MCDONALD, Howard University
THERESA SHAPIRO, University of New Orleans

* Not to appear in *Papers and Proceedings*

2:00 P.M. THE FLEXIBILITY OF WAGES AND PRICES
Chairperson: ROBERT J. GORDON, Northwestern University
Papers: GEORGE AKERLOF, University of California, Berkeley
Inflation: Tales Told by Static Models
WILLIAM D. NORDHAUS, Yale University
The Sources of Worldwide Inflation
MICHAEL L. WACHTER, University of Pennsylvania
The Flexibility of Wages in Postwar Recessions
Discussants: ASSAR LINDBECK, Institute for International Economic Study
DAVID MEISELMAN, Virginia Polytechnic Institute at Reston
DAVID H. SWINTON, State University of New York at Stony Brook

2:00 P.M. INTERNATIONAL ECONOMIC INTERDEPENDENCE: IMPLICATIONS FOR POLICY
Chairperson: ANNE O. KRUEGER, University of Minnesota
Papers: ROBERT BALDWIN, University of Wisconsin
The Effect of Alternative Tax Cutting Rules on the Industrial Composition of U.S. Trade and Employment
THOMAS HORST, The Brookings Institution and Harvard University
Multinational Firms and National Taxation
C. FRED BERGSTEN AND WILLIAM R. CLINE, The Brookings Institution
Implications of Growing Interdependence for Research Agenda
Discussants: GOTTFRIED HABERLER, American Enterprise Institute
HARRY G. JOHNSON, University of Chicago

2:00 P.M. RECENT AND PROSPECTIVE CHANGES IN THE STRUCTURE OF METROPOLIS* (Joint Session with the Real Estate and Urban Economics Association)
Chairperson: CHARLES L. LEVEN, Washington University
Papers: WILLIAM ALONSO, University of California, Berkeley
Demographic Shifts and Urban Structures
ANN SCHNARE, The Urban Institute
Energy, Transportation, and Urban Structure
EDWIN S. MILLS, Princeton University
Land Use Controls and Energy Costs in Urban Areas
JEROME ROTHENBERG, Massachusetts Institute of Technology
Impact of Energy Costs on Intra-Urban Location
Discussant: EUGENE SMOLENSKY, University of Wisconsin

2:00 P.M. ECONOMIC STATUS OF WOMEN IN INTERNATIONAL WOMEN'S YEAR
Chairperson: BARBARA B. REAGAN, Southern Methodist University
Papers: MARY KEYSERLING, Washington, D.C.
National Aspects
(To be announced)
International Aspects
Discussants: NANCY BARRETT, Congressional Budget Office
KENNETH E. BOULDING, University of Colorado
JUANITA KREPS, Duke University

2:00 P.M. EXCHANGE VERSUS GRANT TRANSACTIONS IN ENVIRONMENTAL MODELS (Joint Session with the Association for the Study of the Grants Economy)
Chairperson: KENNETH E. BOULDING, University of Colorado
Papers: MARTIN PFAFF, University of Augsburg, FRG
The Distribution Effects of the Polluter Pays Principle
LLOYD D. ORR, Indiana University
Incentive for Innovation as the Criterion for Effluent Charges
HAROLD BRUMM, California State University, Los Angeles
The Role of Government in the Allocation of Resources to Technological Innovation
RON D. WHITE, Wichita State University
The Anatomy of Nonmarket Failure: A Structure for Analyzing Policy Decisions
Discussants: A. ALLAN SCHMID, Michigan State University
JANOS HORVATH, Holcomb Research Institute, Butler University

---

* Not to appear in *Papers and Proceedings*

2:00 P.M. HISTORY OF POLITICAL ECONOMY AND BIO-ECONOMICS* (Joint Session with the History of Economics Society)
Chairperson: CARL G. UHR, University of California, Riverside and Vice President of the History of Economics Society
Papers: NICHOLAS GEORGESCU-ROEGEN, Vanderbilt University
Economics or Bio-Economics?
WILLIAM D. GRAMPP, University of Illinois at Chicago Circle
Economists and Politicians: Some Cautionary History
Discussants: ROBERT M. LARSEN, University of Utah
JOAN MCCREA, University of Texas at Arlington

2:00 P.M. CURRENT ISSUES IN DEFENSE ECONOMY*
Chairperson: JOHN KOEHLER, Congressional Budget Office
Papers: JOHN DEPRES, The RAND Corporation
Political Economy of Modern Military Competition
MICHAEL REICH, University of California, Berkeley
Obstacles to Controlling Military Spending
BYRON DOENGES, Arms Control and Disarmament Agency
International Trade in Arms
Discussants: JOHN STEINBRUNER, John F. Kennedy School of Government
ROBERT L. SLIGHTON, U.S. Treasury

2:00 P.M. HOW CAN GOVERNMENT NEEDS FOR POLICY RESEARCH BE BETTER MET?*
Chairperson: CHARLES C. HOLT, The Urban Institute
Panelists: ALICE M. RIVLIN, Congressional Budget Office
CHARLES L. SCHULTZE, The Brookings Institution
MICHAEL H. MOSKOW, Department of Housing and Urban Development
ERWIN HARGROVE, The Urban Institute and Brown University
WILLIAM NISKANEN, University of California, Berkeley

2:00 P.M. THE ECONOMIC ORGANIZATION OF SOCIALIST AGRICULTURE (Joint Session with the Association for Comparative Economic Studies and the American Agricultural Economics Association)
Chairperson: ARCADIUS KAHAN, University of Chicago
Papers: D. GALE JOHNSON, University of Chicago
An Economic Model for Socialist Agriculture
ANTHONY TANG, Vanderbilt University
Organization and Performance of Chinese Agriculture
ZBIGNIEW FALLENBUCHL, University of Windsor
Incentives and the Organization of East-European Agriculture
ROY LAIRD, University of Kansas
Central Controls, Farm Size and the Zveno
ROBERT STUART, Douglass College
The Socialist Organizational Model and the Developing Economies

4:00 P.M. BUSINESS MEETING

8:00 P.M. PRESIDENTIAL ADDRESS
Chairperson: GEORGE LELAND BACH, Stanford University
Speaker: ROBERT AARON GORDON, University of California, Berkeley

Tuesday, December 30, 1975

8:30 A.M. IN ANTICIPATION OF NATIONAL HEALTH INSURANCE: ANALYSES OF HEALTH COST CONTAINMENT PROGRAMS* (Joint Session with the Health Economics Research Organization)
Chairperson: DONALD E. YETT, University of Southern California
Papers: CLIFTON R. GAUS AND BARBARA S. COOPER, Social Security Administration
Evaluation of Medicaid Experience in Health Maintenance Organizations
WILLIAM D. FINKLE, Southern California Kaiser Foundation and Health Plan
Quality of Care Versus Cost Containment: Implication for Professional Standards Review Organizations (PSROs)
RALPH E. BERRY, JR., Harvard University
Evaluation of Prospective Hospital Reimbursement in New York
Discussants: PAUL J. FELDSTEIN, University of Michigan
ROYAL A. CRYSTAL, Bureau of Quality Assurance, Department of Health, Education, and Welfare
JUDITH R. LAVE, Carnegie-Mellon University

* Not to appear in *Papers and Proceedings*

8:30 A.M. PLANNING FOR THE 1980 CENSUS*
Chairperson: RICHARD RUGGLES, Yale University
Papers: DAVID L. KAPLAN, Bureau of the Census
Overall Issue and Problems
MEYER ZITTER, Chief of the Population Division
Subject Content of the Population Census
ARTHUR F. YOUNG, Chief of the Housing Division
Subject Content of the Housing Census

8:30 A.M. ALLOCATIONAL EFFICIENCY OF SECURITY MARKETS UNDER UNCERTAINTY* (Joint Session with the American Finance Association)
Chairperson: ROBERT LITZENBERGER, Stanford University
Papers: SANFORD GROSSMAN, Stanford University
Incentives for Information Gathering in Competitive Stock Markets where Investors have Diverse Knowledge
NEILS NIELSEN, Copenhagen School of Economics and Business Administration
The Investment Decision of the Firm Under Uncertainty
STEPHEN ROSS, University of Pennsylvania
Behavior of Agents, Efficiency and Uncertainty
MARK RUBINSTEIN, University of California, Berkeley
The Strong Case for the Generalized Logarithmic Utility Model as the Premier Model of Financial Markets
Discussants: ALAN KRAUS, University of Washington
HAYNE LELAND, University of California, Berkeley
JOSEPH STIGLITZ, Stanford University
FRED GRAUER, Massachusetts Institute of Technology

8:30 A.M. ECONOMIC EDUCATION
Chairperson: PHILLIP SAUNDERS, University of Indiana
Papers: ELISABETH ALLISON, Harvard University
Self-Paced Student Learning at Harvard
DARRELL LEWIS AND WILLIAM BECKER, University of Minnesota
The Teacher Training Program for New Ph.D.s
STEPHEN LONG, Franklin and Marshall College, AND RICHARD HANSEN, University of Nebraska
Participants' Views of the Teacher Training Program
Discussants: JOHN SIEGFRIED, Vanderbilt University
CAMPBELL McCONNELL, University of Nebraska
DAWN ELVIS, Fisk University

8:30 A.M. DYNAMICS OF THE POVERTY AND WELFARE POPULATION*
Chairperson: HEATHER ROSS, Office of Economic Analysis, U.S. Department of the Interior
Papers: DAVID LYON AND OTHERS, staff members, The New York City Rand Institute
A Dynamic Analysis of the New York City Welfare Rolls
MICHAEL WISEMAN, University of California, Berkeley
The Dynamics of the Alameda County, California Welfare Rolls
BARRY L. FRIEDMAN AND LEONARD J. HAUSMAN, Brandeis University
Work and Welfare Patterns in Low Income Families
FRANK LEVY, University of California, Berkeley
How Big is the American Underclass?
Discussants: HENRY AARON, The Brookings Institution
MICHAEL BARTH, University of Wisconsin and Department of Health, Education, and Welfare

10:30 A.M. THE LAST GREAT DEPRESSION AND THE PRESENT ONE
Chairperson: ANNA J. SCHWARTZ, National Bureau of Economic Research
Papers: PETER TEMIN, Massachusetts Institute of Technology
Lessons for the Present from the Great Depression
ARTHUR GANDOLFI AND JAMES R. LOTHIAN, First National City Bank in New York
Depression, Uncertainty, and the Demand for Money
HEYWOOD FLEISIG, Federal Reserve System
The International Recycling Problem: the Interwar Years and Today

---

* Not to appear in *Papers and Proceedings*

Discussants: Robert A. Gordon, University of California, Berkeley
Sidney Davis, Atlanta University
Michael R. Darby, University of California, Los Angeles

10:30 A.M. Economics of Information and Innovation*
Chairperson: Joel Goldhar, National Science Foundation
Papers: William Baumol, Princeton University and New York University
Public Good Attributes of Information and its Optional Pricing
Fritz Machlup, New York University
The Economic Strangulation of the Science Information Enterprise
Edwin Mansfield, University of Pennsylvania
Returns from New Industrial Technology
Discussants: Sanford Berg, University of Florida
Nestor Terleckyj, National Planning Association
Robert Willig, Bell Telephone Laboratories

10:30 A.M. International Capital Markets and Foreign Exchange: New Directions of Research (Joint Session with the American Finance Association)
Chairperson: (To be announced)
Papers: Kalman J. Cohen and others, Duke University and New York University
The Determinants of Common Stock Returns Volatility: An International Comparison
Michael Adler and Bernard Dumas, Columbia University
Variations in the Demand for Stocks and Forward Currency Contracts in an International Capital Asset Market with Default Risk
Richard W. Roll and Bruno H. Solnik, Centre d'Enseignment Superieur des Affaires
Interest Rates and Exchange Rates
Discussants: Tamir Agmon, Tel Aviv University
Donald Lessard, Massachusetts Institute of Technology
Haim Levy, Jerusalem University

10:30 A.M. Expectations and Aggregate Dynamics* (Joint Session with the Econometric Society)
Chairperson: Robert E. Lucas, Jr., University of Chicago
Papers: Robert J. Barro, University of Rochester
Indexation in a Rational Expectation Model
Edmund S. Phelps and John Taylor, Columbia University
Rational Expectations: No Bar to Monetary Stabilization Policy
Thomas Sargent, University of Minnesota
Estimates of the Demand for Money in Hyper Inflation
Discussants: Stanley Fischer, Massachusetts Institute of Technology
Bennett McCallum, University of Virginia
Robert Shiller, University of Pennsylvania

10:30 A.M. New Directions in Health Policy Research* (Joint Session with the Health Economics Research Organization)
Chairperson: Victor F. Fuchs, National Bureau of Economic Research
Papers: Karen Davis, The Brookings Institution, and Ray Marshall, University of Texas
The Market for Health Care in Rural Areas
Mark Pauly, Northwestern University
The Role of Demand Creation in the Provision of Health Care Services
Uwe Reinhardt, Princeton University
Health Manpower Planning in a Market Context
Discussants: Herbert E. Klarman, New York University
Stuart Altman, U.S. Department of Health, Education, and Welfare
Barbara Kehrer, Mathematica

Note: In addition to these sessions of invited papers the American Economic Association is also arranging for several sessions of contributed papers, including some sponsored with the Econometric Society. The scheduled times and other details will be given in the final program to be distributed at the meetings.

* Not to appear in *Papers and Proceedings*

ANNOUNCEMENTS

On March 14, 1975 the Executive Committee of the American Economic Association approved the following changes in the financial operation of the *American Economic Review* and *Journal of Economic Literature.*

a) The discontinuance of free reprints/offprints to authors of material appearing in the *American Economic Review* and *Journal of Economic Literature.* Reprints/offprints will continue to be sold at prices which cover the relevant costs. This change will begin with the December 1975 issues.

b) A differential submission fee for authors who are not members of the American Economic Association. Beginning July 1, 1975, the submission fee for manuscripts submitted to the *American Economic Review* will be fifteen dollars ($15) for members and thirty dollars ($30) for nonmembers.

c) A postage surcharge for mailing of material outside the United States. This surcharge will equal the difference between mailing costs inside and outside the United States. It will be added to new subscription and membership bills January 1, 1976.

d) A page charge for articles, shorter papers, notes, comments, and replies published in the *American Economic Review* and in the *Journal of Economic Literature.* The page charge is payable by the institution or granting agency supporting the research. Payment of this charge is not a prerequisite for publication, nor are authors expected to pay these charges themselves. The charge will be twenty-five dollars ($25) per printed page, and will go into effect with manuscripts accepted after July 1, 1975.

The eighty-eighth annual meeting of the American Economic Association will be held in Dallas, Texas, December 28–30, 1975. The Employment Registry and Center will open December 27. The meeting was originally scheduled for October, but has been changed in the interest of attracting greater attendance.

Nicolaus and Associates have been appointed the official travel coordinator for the Dallas meetings of the Allied Social Science Associations. Group air fares may be arranged from your city and for groups as small as fifteen. These fares usually run about 25 percent below regular coach fare. Some examples using current fares subject to change are:

	Coach	*Group*
New York–Dallas-New York	$236.73	$159.73
Des Moines–Dallas–Des Moines	124.73	99.73
San Francisco–Dallas–San Francisco	252.73	202.73

Flights will be arranged for other cities if enough individuals show interest. Air reservation forms and general information on flights and costs will be mailed to you in October with the preregistration material. In the meantime if you have any questions on group flights, please call Nicolaus and Associates collect at 817-461-1622, or write them at 1201 N. Watson Road, Suite 179, Arlington, Texas 76011.

Five changes in the bylaws have been approved by the Executive Committee and are being submitted to the membership for possible adoption by a mail ballot. A full description of the proposed changes together with the ballot have been included in the mailing of material (including ballots) related to the election of next year's officers. Three of the changes concern the dues structure and classes of membership. On account of the poor financial condition of the Association (see this *Review*, May 1975, pages 460–63 and 467–74), increased revenues are needed. It is proposed to increase the progressivity of the dues structure, putting the burden primarily on those with higher incomes; to double the dues of family members; and to phase out the category of life members. Another proposal would give the Executive Committee the option of submitting to the entire membership for mail vote any resolution adopted at an annual meeting by a vote of less than 5 percent of the members (counting negative as well as positive votes). The fifth proposal would remove the limit of twelve to the number of elected Distinguished Fellows.

Resolutions for Consideration at the Annual Business Meeting

The Executive Committee at its meeting on March 8, 1974, voted to require that, to be considered at the annual business meeting, proposed resolutions must be submitted to the Secretary at least one month in advance in writing with signatures of the proposer and the second, both of whom must be members in good standing. The Secretary will reproduce the proposed resolutions and make copies available in advance of the meeting. The next business meeting will be on December 29, 1975. The deadline for proposed resolutions is, accordingly, November 29. They should be sent to the Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

The Asia Foundation has awarded the American Economic Association a grant to assist graduate students and visiting scholars from Asia currently at *U.S.* institutions to attend the annual meeting of the association. The 1975 meeting will be held in Dallas, Texas, December 28–30. Approximately 8 travel grants up to $150 each will be awarded. Write the American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212 for an application form. To be considered for a travel grant, completed forms must be received by November 7, 1975.

Call for Papers for the 1976 Meetings

Members wishing to give papers or make suggestions for the program for the meetings to be held in Atlantic City, September 16–18, 1976, are invited to send their ideas to Rendigs Fels, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212. Although most of the sessions sponsored by the American Economic Association will consist of invited papers, there will also be several sessions of noneconometric contributed papers. Proposals for invited sessions should be submitted as soon as possible, as this phase of program planning will be completed by mid-autumn. To be considered for the contributed sessions, abstracts of proposed (noneconometric) papers must be received by the Secretary no later than February 1, 1976. Economists wishing to give papers on econometrics or economic theory may submit abstracts to the Econometric Society, which meets with the American Economic Association and annually schedules a substantial number of contributed sessions.

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The deadlines for applications to be received in the office of the American Economic Association are: for meetings scheduled between June and September, February 15; for meetings scheduled between October and January, June 15; for meetings scheduled between February and May, October 15. Application forms may be obtained from Rendigs Fels, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

1976–77 FDIC Graduate Fellowships

The Federal Deposit Insurance Corporation is currently accepting applications for its 1976–77 fellowships which support research in banking, finance, and economics. Graduate students who will have completed all requirements for the Ph.D. (except the dissertation) by October 1, 1976, and are about to begin writing their doctoral dissertations in the areas of economics, banking, and finance are invited to apply for this year's fellowships. The maximum fellowship award is $6,000 (plus tuition), with an additional award of $500 if the dissertation is completed and accepted within the period covered by the fellowship. The awards cover a period of 12 to 15 months, beginning any month between July and October 1976, and ending no later than September 30, 1977. Requests for fellowship applications should be directed to: Federal Deposit Insurance Corporation, Division of Research, 550 17th Street, N.W., Washington, D. C. 20429.

The Social Science History Association has been organized to further the interests of historians and social scientists concerned with the application of social science theory and method in historical context. Members of the Association plan a wide range of activities, including a publication program, national and regional conferences, the fostering of special interest networks, data resource and curriculum development and related action. Charter, regular, and student memberships ($100, $15, and $8) are available: write Jerome M. Clubb, Executive Secretary, SSHA, Center for Political Studies, University of Michigan, P.O. Box 1248, Ann Arbor, Michigan 48106. Robert Swierenga, Department of History, Kent State University, Kent, Ohio 44240, editor of the Association Journal, is now accepting manuscripts for review for publication in the journal.

Economists spending time in Europe desiring lecturing appointments in Common Market countries are urged to write to Mr. William Zavis, Deputy Public Affairs Counselor, U.S. Mission to the European Communities, 23 Avenue des Arts, 1040 Brussels, Belgium.

The first African Conference on Informatics in Administration will be held in early 1976. Individuals interested in participating or preparing research papers to be presented should contact Klaus D. Grimm, Special Research Consultant, State of California, 745 Franklin Street, Suite 410, San Francisco, California 94102.

A bicentennial conference, "Adam Smith and the Wealth of Nations, 1776–1976," will be held at Eastern Kentucky University in the spring of 1976, tentatively March 26–28. Scholars in the fields of history, economics, philosophy, political science, and any other field touching on the wide-ranging concerns of Smith's writings are invited to submit proposals for papers. Interested persons should write to Professor William R. Morrow, Department of Economics, Eastern Kentucky University, Richmond, Kentucky 40475.

A conference, "American Re-Evolution," will be held March 19–21, 1976, at the Arizona Inn, Tucson, sponsored by the Department of Economics of the University of Arizona, Criterion Studies, and the Public Choice Society. Authors of papers which explore new ways to "govern" ourselves, or isolate causes of our current difficulties, are invited to submit copies no later than November 25, 1975, or preliminary outlines by no later than October 25, to Professor Richard D. Auster, Department of Economics, University of Arizona, Tucson, Arizona 85721. Travel and housing expenses of participants in the conference will be paid.

The second annual Virginia Conference on Urban Studies, "The Urban South—Perspective '76," will be held February 12–13, 1976 at Norfolk State College. Urban specialists from all the social sciences are invited to participate. For further information, write Professor Jesse Pendleton, Department of Geography, Norfolk State College, or Professor Carl Abbott, Department of History, Old Dominion University, Norfolk, Virginia 23508.

Under a joint program of the Social Science Research Council and the American Council of Learned Societies, fellowships are offered for nine to eighteen months of dissertation research on contemporary Western European affairs. Applications are invited from students in all social sciences and humanities, but particular attention is given to disciplines in which relatively less attention has been devoted to Western Europe, such as anthropology, economics, social psychology, and sociology. Requests for further information and application forms should be sent to Social Science Research Council, Western European Program, 605 Third Avenue, New York, New York 10016.

The Southern Regional Science Association will hold its 1975 meetings in Richmond, Virginia, on April 8–9, 1976. Scholars interested in presenting papers on any subject involving analysis of the spatial dimensions of human activity are invited to submit one-page abstracts by October 1, 1975 to the program chairman, Professor Monroe Newman, Department of Economics, Pennsylvania State University, University Park, Pennsylvania 16802.

The purpose of the History of Economics Society is to promote interest and inquiry into the history of economics and related parts of intellectual history; facilitate communication and discourse among scholars working in the field; and acquaint members of the profession with the scientific, literary, and philosophical tradition of economics. Information about membership in the Society and about a reduced-price subscription to the quarterly journal *History of Political Economy* can be obtained from James L. Cochrane, Secretary-Treasurer, History of Economics Society, University of South Carolina, Columbia, South Carolina 29208.

The Society will hold its next annual conference at Center for Continuing Education, University of Chicago on May 21–23, 1976. The primary but not sole theme of the conference will be Adam Smith's *Wealth of Nations*. Anyone wishing to present a paper should submit an abstract (two copies) together with a *separate* sheet containing the following information: Author's name, address, professional affiliation, position, and telephone number; title of paper; and whether or not the author is a member of the Society. This must be received by November 15, 1975. Persons wishing to serve as discussants are invited to submit their name, address, professional affiliation, position, telephone number, and major areas of interest *within* the history of economics. All communications regarding the conference should be addressed to Professor George J. Stigler, Haskell Hall, University of Chicago, Chicago, Illinois 60637.

On May 20, 1976, the Economics Department of the City College of New York will sponsor an all-day conference on "The Economics of Information." The object of the conference is to stimulate research that is relevant to current public issues and policies and to economic analysis. Persons interested in reading papers at the conference are invited to submit them to Professor Robert D. Leiter or Professor Malcolm Galatin, Department of Economics, City College of the City University of New York, Convent Avenue and West 138 Street, N.Y. 10031. Papers delivered at the conference are scheduled for publication in the fourth annual conference volume of the department.

The meeting of the Gesellschaft für Wirtschafts-und Sozialwissenschaften (Verein für Socialpolitik), "Social Problems of Modern Industrial Societies," will be held September 13–15, September 1976 in Augsburg. The Society invites proposals for papers on: Structural unemployment; Pollution; Urbanization; The declining birthrate and the tendency towards small families; The systems of social security in relation to the social goals of redistribution and security, and the cost explosion in health services; Changes in the degree of unionization, its causes and its importance in union policy, and the strike as an instrument of union policy; The manpower approach to educational planning in developed economies, and the efficiency of the various systems of professional training schools; The conflict between redistribution and stabilization goals in fiscal policy, and the Social Budget as an instrument of public social policy. Applications are to be submitted to Professor Dr. B. Külp, Institut für Allgemeine Wirtschaftsforschung, D-7800 Freiburg i.Br., Werthmannplatz 1.

Visiting Economics Schclars Program

The Executive Committee of the American Economic Association has approved a Visiting Economics Scholars Program. The program has the following objectives: (1) to stimulate interest and help develop skills in economics among undergraduates in colleges and universities through short-term (one or two days) visits by distinguished members of the profession; (2) to provide opportunities for faculty members at the host institutions to discuss their teaching and research problems with the visitor. The host institution is expected to cover all travel and living expenses associated with the visit and to pay its usual honorarium. For more information, contact C. Elton Hinshaw, Assistant Secretary-Treasurer, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

Deaths

John C. Daniel, lecturer, department of economics, Rutgers College, Dec. 7, 1974.

Joseph S. Davis, professor emeritus of economic research, Food Research Institute, Stanford University, Apr. 23, 1975.

Leo Fishman, professor of economics, West Virginia University, Apr. 4, 1975.

Charles B. Friday, professor of economics and a former president of the Western Economic Association, Oregon State University, Apr. 16, 1975.

Calvin B. Hoover, Duke University.

George W. Stocking, June 7, 1975.

Retirements

Andrew J. Bartley, professor of economics, North Carolina State University, May 1975.

Frank T. de Vyver, Duke University.

Jean O. M. van der Mensbrugghe, advisor, International Monetary Fund, Mar. 31, 1975.

James S. Youtsler, professor and chairman, department of economics, Skidmore College, July 1975.

Visiting Foreign Scholars

Robin Marris, King's College, Cambridge University: visiting professor of economics, University of Maryland, 1975–76.

Ezra J. Mishan, London School of Economics: visiting professor of economics, University of Maryland, fall semester 1975.

David K. Round: visiting lecturer, department of economics, Duke University.

Promotions

George J. Bossy: manager, foreign department, Federal Reserve Bank of New York, Feb. 21, 1975.

Robert M. Fearn: professor of economics and business, North Carolina State University, July 1975.

Joseph W. Ford: professor of economics, St. Francis College, Sept. 1, 1975.

A. Ronald Gallant: associate professor of statistics and economics, North Carolina State University, July 1975.

Daniel A. Graham: associate professor, department of economics, Duke University.

Christopher I. Higgins: assistant secretary, economic Branch, Australian Treasury, Apr. 1975.

George R. Juncker: chief, Bank Analysis Division, Federal Reserve Bank of New York, Jan. 9, 1975.

Hugh L. Liner: extension professor of economics and business, North Carolina State University, July 1975.

Jerome L. McElroy: associate professor of economics, College of the Virgin Islands, Sept. 1975.

Carlisle E. Moody: associate professor, College of William and Mary, Sept. 1975.

Richard W. Nelson: chief, Banking Studies Division, Federal Reserve Bank of New York, Jan. 9, 1975.

Clayne L. Pope: associate professor of economics, Brigham Young University, Sept. 1975.

Hiroki Tsurumi: professor of economics, department of economics, Rutgers College, July 1, 1975.

Joan G. Walters: professor of economics, Fairfield University, Sept. 1974.

Administrative Appointments

Roger E. Bolton: acting chairman, department of economics, Williams College, Jan. 1975.

Thomas M. Freeman: director, Office of Institutional Research, Michigan State University, Mar. 1, 1975.

Martin A. Garrett: chairman, department of economics, College of William and Mary, Feb. 1, 1975.

George J. Neimanis: chairman, department of economics and commerce, Niagara University, June 1, 1975.

Clayne L. Pope: chairman, department of economics, Brigham Young University, Sept. 1975.

Kenan Sahin: associate chairman, department of management science and management information systems, University of Massachusetts.

Sidney C. Sufrin: chairman, department of general business and finance, School of Business Administration, University of Massachusetts.

Lawrence A. Weiser: chairman, department of economics and business administration, University of Wisconsin, Stevens Point, Aug. 25, 1975.

New Appointments

Joseph M. Anderson, Harvard University: assistant professor of economics, Williams College, July 1, 1975.

Kenneth C. Baseman, Stanford University: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Douglas H. Blair: lecturer, department of economics, Rutgers College, July 1, 1975.

Bruce Bolnick: assistant professor, department of economics, Duke University.

Yale Braunstein: assistant professor, department of economics, New York University, Sept. 1974.

James M. Broadus, Yale University: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Charles C. Brown, Harvard University: assistant professor of economics, University of Maryland, Aug. 15, 1975.

Marie E. Brown, University of California, Los Angeles: assistant economist, economics department, The Rand Corporation, Dec. 1974.

Anne J. Bynoe: lecturer, department of economics, Rutgers College, July 1, 1975.

Robert L. Clark: assistant professor of economics and business, North Carolina State University, fall 1975.

John F. Cogan, University of California, Santa Barbara: associate economist, economics department, The Rand Corporation, July 1975.

Neal P. Cohen: assistant professor of economics, St. Louis University, Sept. 1, 1975.

Eugene P. Durbin, Technology Service Corporation: senior economist, economics department, The Rand Corporation, Jan. 1975.

Philip M. Eisenstat, Northwestern University: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Norman Familant, University of Virginia: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Richard S. Fenwick, Jr., Kansas State University: associate professor of economics and business, North Carolina State University, July 16, 1975.

Gerald L. Fralick, U. S. Postal Rate Commission: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

John F. Geweke: assistant professor, department of economics, University of Wisconsin, Madison.

Marion H. Gillim: professor of economics, Eastern Kentucky University, Aug. 1974.

Peter T. Gottschalk, University of California, Santa Cruz: assistant professor of economics, Mount Holyoke College, fall 1975.

Frederick W. Gramlich, Harvard University: staff economist, Economics Policy Office, Antitrust Division, U.S. Department of Justice.

Frederick H. deB. Harris: assistant professor of economics, College of William and Mary, Sept. 1975.

Donald R. Haurin, University of Chicago: assistant professor, Ohio State University.

Ronald A. Heiner: assistant professor of economics, Brigham Young University, Sept. 1975.

Peter H. Henning, University of Michigan: assistant professor, Wayne State University, Sept. 1975.

Susan Hosek: associate economist, economics department, The Rand Corporation, July 1975.

John T. Hoven, University of Wisconsin: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Joseph P. Hughes: assistant professor, department of economics, Rutgers College, July 1, 1975.

James B. Kearl: assistant professor of economics, Brigham Young University, Sept. 1975.

Kenneth J. Kopecky, Ohio State University: economist, Federal Reserve Board, Sept. 1975.

Arthur Kraft: professor of management science, University of Nebraska, Lincoln, Aug. 1975.

Martha J. Langer, Yale University: department of economics, Mount Holyoke College, fall 1975.

Augusto A. Legasto, Jr.: assistant professor, department of economics, Rutgers College, July 1, 1975.

Edgar W. Leonard: assistant professor of economics and business, North Carolina State University, fall 1975.

Charles Lieberman, University of Pennsylvania: assistant professor of economics, University of Maryland, Aug. 1974.

Martin P. Loeb: assistant professor of economics and business, North Carolina State University, fall 1975.

Jerome L. McElroy, College of the Virgin Islands: senior research associate and socioeconomic research coordinator, Caribbean Research Institute, Sept. 1974.

J. Michael McGuire: assistant professor of economics, St. Louis University, Sept. 1, 1975.

Willard G. Manning, Jr., Harvard University: associate economist, economics department, The Rand Corporation, July 1975.

Neil W. Mather, University of Wisconsin: assistant professor, Wayne State University, Sept. 1975.

Edgar O. Olsen: visiting associate professor of economics, University of Wisconsin, Madison; project associate, Institute for Research on Poverty.

A. Mead Over, Jr., University of Wisconsin: assistant professor of economics, Williams College, July 1, 1975.

John D. Owen, New School for Social Research: professor, Wayne State University.

Wayne D. Perry, Carnegie-Mellon University: associate economist, economics department, The Rand Corporation, June 1975.

Andrew Popper: economist, Foreign Research Division, Federal Reserve Bank of New York, Mar. 20, 1975.

Arturo C. Porzecanski, University of Pittsburgh: economist, Centro de Estudios, Monetarios Latinoamericanos, Mexico City, Sept. 1, 1975.

David L. Roberts: assistant professor, department of economics, Rutgers College, July 1, 1975.

Samuel Rosenberg, University of California, Davis: assistant professor of economics, Williams College, July 1, 1975.

Clark G. Ross: assistant professor of economics, College of William and Mary, Sept. 1975.

Kevin T. Saiki: instructor, economics, U.S. International University, Makawao, Hawaii.

David A. Schauer: assistant professor of economics and finance, University of Texas, El Paso, Sept. 1, 1975.

Jeff A. Schnepper: lecturer, department of economics, Rutgers College, July 1, 1975.

Peter Simon, University of Pennsylvania: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Lee I. Sparling, California Institute of Technology: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Gordon R. Storholm: lecturer, department of economics, Rutgers College, July 1, 1975.

Frederick R. Strobel, Federal Bank of Atlanta: associate professor of money and banking, Kalamazoo College, Jan. 1, 1975.

Miguel L. Tejada, Iowa State University: senior specialist, Unit of Technical Change and Transfer of Technology, Organization of American States, Washington, Sept. 1, 1974.

Edward Tower: associate professor, department of economics, Duke University.

T. Dudley Wallace: professor, department of economics, Duke University.

Geraldine A. Walter, University of California, Los Angeles: assistant economist, economics department, The Rand Corporation, Mar. 1975.

Bernard L. Weinstein, State University of New York: senior assistant professor, department of economics, University of Texas, Dallas, Sept. 1975.

Walter J. Wessels: assistant professor of economics and business, North Carolina State University, fall 1975.

Robert C. West, Northwestern University: assistant professor of economics, University of Maryland, Aug. 1974.

Robert W. Wilson, Yale University: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Allen M. Wyse: assistant professor, department of economics, Duke University.

Leaves for Special Appointments

Robert P. Armstrong, International Bank for Reconstruction and Development: economic advisor to the Ministry of Economy and Economic Cooperation, Ford Foundation Investment Planning Project, Arab Republic of Egypt, Feb. 1975.

Leslie E. Grayson, University of Virginia: Ford Foundation award, visiting professor, European Graduate Institute of Business Administration, 1975–76.

Karl D. Gregory, Oakland University: senior staff member, Congressional Budget Office, U.S. Congress, Washington, June 1975.

Ira Horowitz, University of Florida: staff economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice.

William Jaffé, York University: Killam senior research scholarship, 1975–76.

Richard K. Perrin, North Carolina State University: associate economist, CIMMYT, Mexico, Jan. 1, 1975.

Leonard G. Schifrin, College of William and Mary: National Science Fellow, School of Medicine, Stanford University, 1975–76.

Norman P. Swenson, Corps of Engineers: planning associate, Board of Engineers for Rivers and Harbors, Aug. 11, 1974.

Richard E. Sylla, North Carolina State University: senior associate, St. Antony's College, Oxford University, Sept. 1975–June 1976.

Resignations

Ashok Bhargava, University of Wisconsin, Whitewater, May 1975.

Leon M. Ennis, Jr., North Carolina State University: University of North Carolina, Chapel Hill, July 1975.

Thomas O. McCoy, Williams College, June 30, 1975.

Robert C. Rice, University of Hawaii: Monash University, Australia, Aug. 1975.

Henry Thomassen, University of Nebraska, Lincoln.

Rodger Weaver, University of Nebraska, Lincoln, Jan. 5, 1975.

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3×5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

DETENTE AND DOLLARS:

Doing Business with the Soviets

Marshall I. Goldman

This indispensable book by a leading expert in East-West trade, provides the American businessman with the perspective and information he needs to decide whether he too should enter the billion-dollar Soviet market and, if so, how he can do it successfully. Dr. Goldman draws important lessons from his detailed inside account of both costly failures (the great American grain disaster of 1972) and success stories (Armand Hammer and the Pullman Corporation) in doing business with the Soviet Union.
Due June $10.00

HOUSING AND THE MONEY MARKETS

Roger Starr

Here is the first systematic introduction to the money markets as they relate to housing. Now Administrator of New York City's Housing and Development Administration, Mr. Starr describes the various institutions that extend mortgages and shows how they finance housing construction. He explores the relationship between lending institutions and the various government agencies such as the FHA, GINNY MAE, and FANNY MAE that have been set up for channeling savings into mortgages. "Timely as well as valuable.... An excellent primer and a well reasoned policy text for specialists and government officials."—LOUIS WINNICK.

ANARCHY, STATE AND UTOPIA

Robert Nozick

In the most challenging defense of property rights and free enterprise in modern times, Professor Nozick poses, as *Forbes* puts it, "nothing less than a challenge to a central feature of the moral landscape: the state as everybody's mother and father."—*Forbes*. "No contemporary philosopher possesses a more imaginative mind, broader interests, or greater dialectic abilities."—*Harpers*. Published $12.95

WHO SHALL LIVE?

Health, Economics, and Social Choice

Victor R. Fuchs

"A short lucid, uncomplicated explanation of the economics of health care.... No book has demonstrated a better grasp of the *social* context of health and health care, of the idea that central social changes, rather than mere technical tinkering with the system is at issue. Most useful."
—*The New York Times Book Review*.

GUIDE TO GRADUATE STUDY IN ECONOMICS AND AGRICULTURAL ECONOMICS

Guide to Graduate Study in Economics and Agricultural Economics

in the United States of America and Canada

THIRD EDITION

Designed to provide students anticipating graduate study in economics and agricultural economics, and their advisors, with information on available graduate training programs.

Includes descriptions of 236 graduate programs, supplemented by comparative data and information for prospective students, domestic and foreign.

Published by the Economics Institute under the auspices of the American Economic Association, and the American Agricultural Economics Association.

Distributed by:
RICHARD D. IRWIN INC.,
1818 Ridge Road,
Homewood, Illinois 60430

PRICE: $7.50 per copy

"The topics are timely... the materials are pertinent... a welcome contribution."

—Michael Yoshino, Professor of Business Administration, Harvard University.

This is the first in-depth analysis of Japanese business ever written in English.

The authors, both specialists in the field, tell the success story of Japanese business in general and of firms like Sony, Honda, and Mitsubishi in particular. And they explain how the Japanese have managed to incorporate traditional values into industrial empires.

Essential reading for anyone doing business on an international level. Or studying it. $12.00

The Development of Japanese Business, 1600-1973

The ECONOMICS INSTITUTE

SPECIAL PROPAEDEUTIC TRAINING AND ORIENTATION PROGRAM FOI

INTERNATIONAL

Graduate Students

in ECONOMICS and RELATED FIELDS

UNIVERSITY OF COLORADO, JANUARY 19 - AUGUST 18, 1976

With six consecutive sessions beginning January 19, February 23, March 29, May 3, June 7 and July 12, 1976.

The Institute is specially designed for students from other countries who are planning to undertake graduate studies at universities in the United States in economics and related fields, including business and agricultural economics. An intensive and specialized *English* instructional program is progressively substituted by an expanding component of preparatory course offerings in *mathematics, statistics* and *economic theory,* and lectures and research seminars on special field topics including agriculture, business and development. The program also includes field trips and social recreational activities designed to acquaint the participants with campus and community life in the United States.

Admissions to the sessions beginning in January, February, March, and May are restricted to students needing further intensive training in English; those who would score in excess of 500 on the TOEFL at the point of registration should apply for the later (summer) sessions.

Universities and sponsoring agencies are invited to utilize the Institute's Credentials Evaluation Service and its Spring and Summer testing and training programs in their evaluation of candidates for graduate program admissions and related financial support.

Further information and application materials may be obtained from the DIRECTOR, ECONOMICS INSTITUTE, UNIVERSITY OF COLORADO, BOULDER, COLORADO 80302, U.S.A.

Program sponsored by th

American Economic Associatio

in cooperation wit
The American Assembly of Collegiate Schools of Busines

Cambridge, Mass. 02138

Liberal Arts Fellowships in Law

For the academic year 1976–1977 Harvard Law School offers four or five Liberal Arts Fellowships to college and university teachers in the arts and sciences for a year at the Law School. Holders of these Fellowships will have the title of Fellow in Law and . . . (History, Sociology, Political Science, Economics, Philosophy, etc., depending upon their particular discipline).

The purpose of the fellowships is to enable teachers in the social sciences or humanities to study fundamental techniques, concepts, and aims of law, so that, in their teaching and research, they will be better able to use legal materials and legal insights which are relevant to their own disciplines.

Fellowship holders will presumably take at least two first-year courses in law, in addition to more advanced courses, and will participate in a joint seminar. The year of study will not count toward a degree.

The fellowship grant is sufficient to cover tuition and health fees. The Chairman of the Liberal Arts Fellowship Committee will be glad to write a letter to any funding agency to which the applicant has applied describing the Program and indicating the extent of the Committee's interest in inviting the applicant to be a Fellow.

Applications should include a biographical résumé (including academic record and list of publications), a statement explaining what the applicant hopes to achieve through his year of study, and two letters of recommendation to be sent directly by the referees.

Applications for 1976–1977 should be submitted before January 15, 1976, to the Chairman, Committee on Liberal Arts Fellowships, Harvard Law School, Cambridge, Massachusetts 02138.

Awards will be announced before February 15, 1976.

Wiley/Hamilton: Business, but not as usual Hamilton Publishing Company has a new point of view: *yours.* Under the new imprint of Wiley/Hamilton, the four-year-old subsidiary of John Wiley & Sons has assumed responsibility for all college-level publishing activities related to the fields of business and economics.

Consolidation of all business-related textbook publishing into a single publishing unit has made it possible for Wiley to assemble the specialized editorial, marketing, and production talents of three corporate groups: Hamilton, the Wiley College Division, and Melville Publishing Company. Narrowing and deepening their publishing program will enable the Wiley/Hamilton editorial, marketing, and production specialists to direct their undivided attention to your areas of interest. The new Wiley/Hamilton group will offer textbook authors in the economics and business-related disciplines the kind of close personal attention that has been a part of Hamilton's philosophy from the company's inception.

If you have textbook needs, or plan to develop a textbook in your area of interest, consider a company that shares your point of view.

Let Wiley/Hamilton mind *your Business.*

Available:

MACROECONOMICS:

Measurement, Theory, and Policy
By Michael C. Lovell,
Wesleyan University

This is an outstanding text for intermediate and upper-level courses in macroeconomics. Lovell stresses modern theoretical advances in analyzing unemployment, inflation, balance of payments, disequilibrium, business cycles, growth.

Schematic flowcharts show students how the equations which constitute the building blocks of a sequence of models fit together. Each chapter ends with a list of key concepts, exercises, and problems.

1975 $14.95

ECONOMICS AND SOCIETY

By Leonard W. Weiss,
University of Wisconsin, Madison

Some economics books stand out. Among these few, Weiss is simply outstanding.

ECONOMICS AND SOCIETY builds its analysis around supply and demand, and aggregate supply and demand. But the theory remains as straightforward as possible—never presented for its own sake. Rather, concepts are applied to such policy issues as monopoly, discrimination, labor market, balance of payments, and public goods. While kept elementary, every concept is developed in the context of realistic, practical experience...to give your students the major elements of economics in a meaningful, realistic setting.

1975 $10.95

Forthcoming:

MICROECONOMICS ANALYSIS WITH APPLICATIONS

By Robert Y. Awh,
Mississippi State University

Awh offers a balanced, comprehensive coverage of up-to-date intermediate microeconomics, combining a solid treatment of theory with real-world applications.

1976

MACROECONOMICS:

Money, Prices, and Income
By Dudley W. Johnson,
University of Washington

This book presents an integrated approach to macroeconomics; that is, it covers the traditional subject matter, as well as the economics of money and banking, and international monetary economics. It also provides an exhaustive analysis of monetarism versus fiscalism.

November 1975 $11.95 (tent.)

MACROECONOMICS Third Edition

By John Lindauer,
Murray State University

This is a thorough, straightforward, and graphic treatment of macroeconomics. This edition has been revised to provide an up-to-date analysis of the state of the art.

February 1976 $13.95 (tent.)

INTRODUCTION TO ECONOMICS:

An Issues Approach

By Chris Rhoden,
Solano College

Pedagogically sound, extremely readable: Rhoden's INTRODUCTION TO ECONOMICS features objectives, summaries, glossaries, and discussion questions for each chapter—as well as related readings drawn from Business Week, Wall Street Journal, etc. Also included: brain teasers (projects for student research).

This introduction to basic concepts and contemporary issues is perfect for the one-term basic economics course. Available with an Instructor's Manual and a Student Study Guide.

January 1976 $9.95 (tent.)

For your complimentary examination copies, contact your Wiley representative or write to George Thomsen, Dept. 840, at the address below. Please include course title, enrollment and present text.

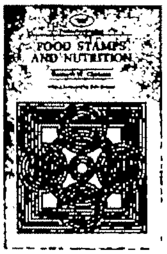
Have Food Stamps Failed?



Food Stamps and Nutrition
by Kenneth W. Clarkson

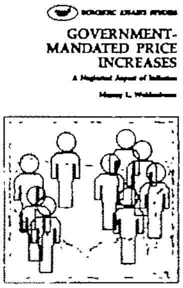
Food stamps do little to improve the nutrition of the poor and serve chiefly as an income subsidy to those who use them, Clarkson charges.

The study surveys Department of Agriculture statistics on the nutritional level of food stamp program participants, measuring the program's benefits to families of different income levels.

85 pages paperback, $3.00

Also from AEI:

Government-Mandated Price Increases
by Murray L. Weidenbaum



The author charges that federal regulatory actions are continually mandating higher prices. Examining such regulatory agencies as the Occupational Safety and Health Administration, Weidenbaum points out that each new benefit generates a new cost for the public. Although regulatory costs are less obvious causes of worsening inflation than budget deficits or "easy" monetary policies, the author says future regulatory actions must be carefully scrutinized to determine their actual costs. **112 pages paperback, $3.00**

OXFORD

Microeconomics

The Analysis of Prices and Markets

DONALD DEWEY, Columbia University. The lively and incisive writing of this text makes it one of the most readable introductions to modern microeconomic theory presently available. The text is the first to deal rigorously with the multiplant enterprise and market concentration. It contains an exceptionally detailed treatment of the theory of the firm, capital and interest, the pricing of factor inputs, and welfare economics. While the axiomatic character of modern microeconomic theory is firmly emphasized, its tools are applied to a wide range of policy problems that interest students: conservation of natural resources, regulations of public utilities, labor legislation, contracts of professional athletes, antitrust, and cost-benefit analysis of public projects.

New books in the
ECONOMIC DEVELOPMENT SERIES
General Editor: GERALD M. MEIER,
Stanford University

Agriculture and Structural Transformation

Economic Strategies in Late-Developing Countries

BRUCE F. JOHNSTON, Stanford University, and **PETER KILBY,** Wesleyan University. In this volume, an agricultural and an industrial economist examine the problems of designing agricultural strategies that will help overcome the acute poverty that characterizes low-income nations. They analyze the interrelationships between agriculture and other sectors of the economy and consider the special problems and opportunities associated with late development. "This is an excellent study of the policy alternatives for late-developing countries in regard to food and agriculture. It appraises the general problem and suggests practical steps for food improvement."—Harold G. Halcrow, University of Illinois

1975 500 pp. graphs and tables cloth $11.95 paper $6.95

Employment, Technology, and Development

AMARTYA SEN, London School of Economics and Political Science. Focusing on the interrelationships among institutions, technology, and employment, the author investigates the institutional factors which affect employment policy making: modes of production, patterns of ownership, and systems of employment. The techniques of project evaluation and shadow pricing are discussed with particular reference not only to institutional features, but also to political feasibility and behavioral characteristics. Professor Sen illustrates his approach in four appendices which reflect India's experience in the field.

Structure of Classical Economic Theory

ROBERT B. EAGLY, State University of New York, Binghamton. "This book offers a clear, concise treatment of the essential structure and analysis of classical economics. It seems to me to be an excellent book . . . to bring together what students get in scattered form from reading several of the classical writers in selection." —Carl G. Uhr, University of California, Riverside. "This book is a significant contribution."—Daniel Coldwell, Memphis State University

1974 160 pp. $7.50

In the following trilogy of policy volumes in international political economy, Professor **GERALD MEIER** offers students a provocative approach to major policy problems involved in establishing a new international economic order. By blending specific source materials with a more general analytical narrative, the author immerses students in a set of actual policy-making situations so they can become concerned with the controversy of foreign economic policy analysis and discover criteria for judging the merits of alternative courses of action. "Excellent format! Students will be delighted. It is a unique way to present the important materials for the subject at hand." —Gerald M. Hampton, Lewis and Clark College

ESSAYS IN
NINETEENTH CENTURY
ECONOMIC HISTORY:

The Old Northwest (1975) $12.00

David C. Klingaman and Richard K. Vedder, Editors, Ohio University

These essays contributed by Donald R. Adams, Richard A. Easterlin, Lowell E. Gallaway, Robert E. Gallman, Don R. Leet, William N. Parker, Roger L. Ransom, Edward H. Rastatter, Lee Soltow, Jeffrey G. Williamson, Richard K. Vedder and David C. Klingaman focus on the factors and the institutions that played important roles in the economic growth of the United States during the nineteenth century. Covering a broad spectrum, the essays analyze the importance of agriculture, land, migration, wealth, banks, canals and the railroad to this growth.

"...the collection is of remarkably high quality and even when most innovative or controversial is always interesting to anyone concerned with the state, the region, or the nation in its nineteenth century experience." – MORTON ROTHSTEIN, University of Wisconsin.

TEXTBOOKS IN ECONOMICS

Announcing:

MONEY AND INFLATION: A Monetarist Approach

J. HUSTON McCULLOCH, Boston College

At last, courses in money and banking can treat the monetarist theory of inflation at considerable depth. In this new supplementary textbook, Professor McCulloch examines both the theoretical and practical aspects of monetary theory from an unabashedly monetarist point of view.

- The treatment of the quantity theory goes far beyond the coverage available in most money and banking textbooks.
- The lively yet precise presentation brings together old and new extensions of the monetarist theory of inflation on a level the undergraduate can master without calculus.
- Problems and solutions reinforce the students' understanding of the critical concepts.

AVAILABLE FOR FALL CLASSES!
September, 1975, *about 120 pages, probable price $2.95*

JAMES D. GWARTNEY, Florida State University

An important new principles textbook.

Available Now:

INTRODUCTION TO URBAN ECONOMICS

DOUGLAS M. BROWN, Georgetown University

In this remarkably unified textbook, Professor Brown makes a detailed survey of the historical realities of urban life. Emphasis is placed on relating economic analysis to contemporary problems.

- The coverage of interurban and intraurban economic analysis requires only a background course in economic principles.
- The economic history of cities, from tribal organizations to the American city today, is surveyed. Particular attention is paid to colonial cities.
- Causes and possible solutions to critical urban problems are examined from the point of view of economic analysis with a minimal use of mathematics.

CLASSICAL ECONOMICS RECONSIDERED

THOMAS SOWELL

The book evaluates classical economics in all its aspects, from its widely misunderstood social philosophy to its microeconomics, macroeconomics, and methodology. The author emphasizes classical economics as a system, treating particular doctrines and propositions as integral parts, rather than as isolated theories. Professor Sowell's reconsideration of the work of economists from Smith to Mill leads him to dispute many interpretations of classical economics in existing literature. $9.00

MULTINATIONAL CORPORATIONS AND THE POLITICS OF DEPENDENCE

Copper in Chile

THEODORE H. MORAN

Using the Chilean copper industry to study the relations between multinational corporations and their host countries in the Third World, the author describes the reaction against *dependencia*, a realization that the fate of the nation hinges on the decisions made by uncontrollable outside forces. *Written under the auspices of the Center for International Affairs, Harvard University* $12.50

CORPORATE GROWTH AND DIVERSIFICATION

CHARLES H. BERRY

As an increasing number of large corporations branch out into many fields of industry, public concern over the lateral extension of their power is aroused. Arguing that entry by large firms into concentrated industries may instead stimulate competition, Charles H. Berry analyzes the effect that such diversification has on corporate growth and on the structure and functioning of industrial markets. $9.50

Volume 89:

EUROPEAN ECONOMIC INTEGRATION

edited by BELA BALASSA, Johns Hopkins University.

1975. about 430 pages. US$ 31.25/Dfl. 75.00. ISBN 0 7204 3193 X.

CONTENTS: The Common Market Experience (B. Balassa). Part I. Integration and Trade. The effects of European economic integration on the production and trade of manufactured products (E. M. Truman). An empirical examination of bilateral trade in Western Europe (S. A. Resnick and E. M. Truman). Trade creation and trade diversion in the European Common Market: An appraisal of the evidence (B. Balassa). Part II. Macroeconomic Implications of Integration. A macro-model for Western Europe (S. A. Resnick). Dynamic properties of the European macro-model (S. A. Resnick). Monetary integration in the European Common Market (B. Balassa). Part III. Policy Aspects of Integration. Structural policies in the European Common Market (B. Balassa). The effects of European economic integration on agriculture (E. Thorbecke and E. Pagoulatos). European integration and the developing countries (M. E. Kreinin). Appendices.

Volume 88:

ESSAYS ON ECONOMIC BEHAVIOR UNDER UNCERTAINTY

edited by M. BALCH, University of Iowa, D. McFADDEN, University of California at Berkeley, and S.WU, University of Iowa.

1974. 452 pages. US$ 51.95/Dfl. 125.00. ISBN 0 7204 3191 3.

The essays in this volume are selected from papers presented at the NSF-NBER Conferences on Decision Rules and Uncertainty. After an introductory essay, the volume is roughly divided into three parts. Part One comprises two papers that deal with the conceptual development of the conditional expected utility framework, Part Two includes five papers on various micro-aspects of behavior under uncertainty while the five papers in Part Three are concerned with welfare economics and general equilibrium.

Volume 87:

FRONTIERS OF QUANTITATIVE ECONOMICS, Vol. II

Papers presented at the Econometric Society Winter Meetings, Toronto, Canada, 1972

edited by MICHAEL D. INTRILIGATOR, University of California, Los Angeles, and DAVID A. KENDRICK, University of Texas at Austin.

1974. 592 pages. US$ 49.95/Dfl. 120.00. ISBN 0 7204 3190 5.

This volume forms a sequel to FRONTIERS OF QUANTITATIVE ECONOMICS – Papers Invited for Presentation at the Econometric Society Winter Meetings, New York, 1969 – edited by M. D. Intriligator (North-Holland, 1971).
The papers are grouped into three parts: The first part consists of papers on economic methodology and theory. The second is concerned with econometric techniques while the third covers quantitative approaches to traditional topics in economics.

Volume 86:

STUDIES IN BAYESIAN ECONOMETRICS AND STATISTICS

In Honor of Leonard J. Savage

edited by STEPHEN E. FIENBERG, University of Minnesota, and ARNOLD ZELLNER, University of Chicago.

1975. 686 pages. US$ 68.75/Dfl. 165.00. ISBN 0 7204 3188 3.

CONTENTS: Econometrics and Bayesian inference. Bayes' theorem and economic theory. Assessing prior distributions. Identification and Bayesian analysis. Applications of Bayesian regression. Missing observation problems. Time series problems. Analyses of simultaneous equation models. Control problems. Reporting results. New developments in estimation. Appendix. Index.

Volume 85:

POPULATION IN ECONOMIC GROWTH

by J. D. PITCHFORD, The Australian National University, Canberra.

1974. 288 pages. US$ 22.95/Dfl. 55.00. ISBN 0 7204 3187 5.

CONTENTS: Models of population growth. The determinants of net fertility. Population and economic growth. Optimum population, scale returns and trade. Optimum population and resources. Population in an optimal growth process. Resources and population control. Age-structure in population models. Conclusion. Index.

Volume 84:

INFLATION IN DEVELOPING COUNTRIES

An Economic Study of Chilean Inflation

by VITTORIO CORBO LIOI, Sir George Williams University, and International Institute of Quantitative Economics, Montreal, Canada.

1974. 300 pages. US$ 29.25/Dfl. 70.00. ISBN 0 7204 3186 7.

CONTENTS: Monetarism, Structuralism and Past Studies of Chilean Inflation. A Quarterly Model for Industrial Prices, Industrial Wages and Inflation. An Annual Study of Inflation. Appendices. References. Index.

Studies in Mathematical and Managerial Economics

Edited by **H. THEIL**, Center for Mathematical Studies in Business and Economics, University of Chicago.

Volume 21: THE THEORY AND MEASUREMENT OF CONSUMER DEMAND, 2

by **H. THEIL**

1976. about 300 pages. In preparation.

CONTENTS: Conditional demand equations under block-independence. Blockwise dependence. Price-disturbance dependence. Statistical and geometric approaches to demand theory. The preference independence transformation. Changes in commodity baskets over time. Equivalent income changes, transitions between budget shares, and other topics. Bibliography. Index.

Volume 20: THE THEORY AND MEASUREMENT OF CONSUMER DEMAND, 1

by **H. THEIL**

1975. 350 pages. Clothbound ed.: US$ 15.95/Dfl. 38.00. ISBN 0 7204 3321 5
Paperback ed.: US$ 9.75/Dfl. 23.00. ISBN 0 7204 3095 X

CONTENTS: Utility theory. The Rotterdam Model. The indirect utility function and the economic theory of index numbers. Market demand. The estimation of complete systems of demand equations. The estimation of larger models. Bibliography. Index.

Volume 19: COST-BENEFIT ANALYSIS AND ECONOMIC THEORY

by **J. LESOURNE**, Chairman of the Board of Metra International.

1975. 530 pages. Clothbound ed.: US$ 41.25/Dfl. 99.00. ISBN 0 7204 3319 3
Paperback ed.: US$ 20.75/Dfl. 49.50. ISBN 0 7204 3097 6

CONTENTS: Introduction. Part I: Theory of Cost-Benefit Analysis. Some basic concepts. The analysis of marginal and structura transformations. The introduction of taxation. The comparison of growth programmes. The introduction of uncertainty as to the future. Information cost and decision cost. Part II: Applications of Cost Benefit Analysis. The industrial sector. The transport sector. Urban planning. Location of industry and the use of land. Public health. Education. General administration. Bibliography.

Volume 18: MANAGEMENT APPLICATIONS OF MODERN CONTROL THEORY

by **A. BENSOUSSAN, E. G. HURST** and **B. NÄSLUND.**

1974. 364 pages. Clothbound ed.: US$ 39.75/Dfl. 95.00. ISBN 0 7204 3318 5

CONTENTS: The need for dynamic management decisions. Introduction to modern control theory. Inventory and production control. Theory of the firm. Optimal maintenance and life of machines. Finance. Marketing. Control of natural resources. Numerical solutions of optimal control problems. Some limitations and further research. Mathematical review. Appendix A: Optimal deterministic control theory. Appendix B: Optimal stochastic control theory. References. Index.

Volume 17: METHODS FOR LINEAR AND QUADRATIC PROGRAMMING

by **C. VAN DE PANNE**, University of Calgary.

1975. 490 pages. Clothbound ed.: US$ 49.95/Dfl. 120.00. ISBN 0 7204 3316 9

CONTENTS: The solution of linear systems. The simplex method for linear programming. Variants of the simplex method. Duality in linear programming and the dual method. Sensitivity analysis and parametric programming. Parametric methods for linear programming. Post-optimality analysis, the reverse simplex method and related methods. Quadratic forms. The simplex and the dual method for quadratic programming. Parametric quadratic programming. Parametric methods for quadratic programming. Some other quadratic programming methods. Multiparametric linear and quadratic programming. Concave quadratic programming. General quadratic programming. The linear complementarity problem, I. The linear complementarity problem, II. Termination for copositive plus and £-matrices. Bibliography. Index.

Volume 16: CLASSICAL OPTIMIZATION: FOUNDATIONS AND EXTENSIONS

by **M. J. PANIK**, Austin Dunham Barney School of Business and Public Administration, University of Hartford, Connecticut, U.S.A.

1975. 260 pages. Clothbound ed.: US$ 26.95/Dfl. 65.00. ISBN 0 7204 3315 0
Paperback ed.: US$ 17.50/Dfl. 42.00. ISBN 0 7204 3081 X

CONTENTS: Mathematical foundations I. Mathematical foundations II. Global and local extrema of real-valued functions. Global extrema of real-valued functions. Polynomial approximation of real-valued functions. Local extrema of real-valued functions. Inflection points of real-valued functions. Convex and concave real-valued functions. Constrained optimization – a single equality side-relation. Constrained optimization – a generalization of the technique of Lagrange to *m* equality side-relations. Kuhn-Tucker theory – an introduction. Kuhn-Tucker theory – a generalization to *m* inequality side-relations. Kuhn-Tucker theory with mixed constraints. Bibliography.

Volume 15: ECONOMIC STABILIZATION POLICY – METHODS IN OPTIMIZATION

by **B. M. FRIEDMAN**, Assistant Professor of Economics, Harvard University.

1975. 394 pages. Clothbound ed.: US$ 33.50/Dfl. 80.00. ISBN 0 7204 3317 7

CONTENTS: Introduction. The econometric model. Point linearization. Subinterval linearization. The dynamic policy multipliers. Quadratic optimization – The level I problem. Piecewise quadratic optimization – The level II problem. Endogenous time horizon optimization – The level III problem. Applications to stabilization policy. Retrospective and prospective. Appendices A: List of Wharton model variable symbols. B: Linearized coefficient values for the Wharton model. C: Proof of piecewise quadratic convergence in the scalar case. D: The TRIOPT Algorithm. E: Card input guide for TRIOPT.

Robert L. Heilbroner
THE WORLDLY PHILOSOPHERS
The lives, times and ideas of the great economic thinkers
Completely revised for the Seventies
Fourth Edition

Heilbroner, Robert L.

THE WORLDLY PHILOSOPHERS: The Lives, Times and Ideas of the Great Economic Thinkers
Fourth Edition, Revised for the 1970's

"The first edition of this exciting book was published in 1953. In his introduction Heilbroner tells us that it is the 'search for order and meaning of social history that lies at the heart of economics. Hence [this] is the central theme of the book.' He achieves his objectives in a brilliant lucid manner. There is no more readable book available as an introduction to the great economists of the last 200 years. This fourth edition is substantially the same as earlier ones with the exception of Chapter 10 which deals with 'The modern world.' Because contemporary problems and trends change as well as what leading economists think about these problems, the content and emphasis of this chapter change with each new edition. Heilbroner has included 'A guide to further reading' with brief comments about the books that he suggests." —*Choice.*

New Books in Economics

Competition Policy
European and International Trends and Practices

A. E. Walsh and John Paxton

An important up-to-date reference for all those interested in the study of marketing goods, both with the European Economic Community and the remainder of the world's competitive economies.

Published 1975 200 pages $19.95, cloth

Development, Underdevelopment and the Law of Value
A Marxist Analysis

Geoffrey Kay

Considers the problem of underdevelopment through an analysis of the law of value as proposed and elaborated by Karl Marx.

Published 1975 208 pages $13.95, cloth

Economic Policies and Social Goals
Aspects of Public Choice

A. J. Culyer, editor

Presents a closely integrated series of original essays on substantive problems in social policy.

Published 1975 308 pages $25.00, cloth

Economic Theory and the Developing Countries
A. K. Dasgupta

Emphasizes the historical context of economic development and looks at the problems of development as they appear to the developing nations themselves.

Published 1975 250 pages $14.95, cloth

Inflation, Saving, and Growth in Developing Countries
A. P. Thirlwall

Brings together for the first time the role of monetary factors in the development process and presents old and new empirical evidence of the dependence of growth on saving and investment.

Published 1975 272 pages $19.95, cloth

Negotiating on Non-Tariff Distortions of Trade
The EFTA Precedents

Robert Middleton

Presents the methods developed by the EFTA for elimination of non-tariff distortions of trade and provides valuable guidance for the conduct of trade negotiations at multilateral and regional levels.

Published 1975 208 pages $18.95, cloth

The New Mercantilism
Harry G. Johnson, editor

Essays by leading economists examine the history of mercantilism, the state of mercantilism today, foreign trade and investment, regional economics, and the current monetary crisis.

Published 1975 128 pages $17.95, cloth

World Monetary Crisis
Peter Coffey

An analytical and critical examination of the world monetary order stressing both political and economic factors.

Published 1975 128 pages $14.95, cloth

Join the American Economic Association

Membership includes:

- a subscription to both *The American Economic Review* (quarterly) plus May, *Papers and Proceedings* and the *Journal of Economic Literature* (quarterly)
- annual ballots and nomination forms for elected officers of the Association
- preregistration material and announcement of the annual meeting of the Allied Social Science Associations
- announcements of special interest to members, such as the life insurance program started in 1973; new book offerings, etc.

Application for Membership

Please enroll me as a member of the American Economic Association. 1975 annual rates: Regular—$23; Family, two or more living at same address, second membership without publications—$2.30; Junior, *registered student $11.50/payable yearly; for a maximum of three years; Subscribing—$27.50; Contributing—$57.50; Life—$460. All dues payable in U.S. currency. Memberships are not entered until payment has been received. (Under the terms of a resolution passed at the annual meeting of members of the American Economic Association on Dec. 29, 1973. $18.40 of the annual membership dues is considered as payment for the AER and JEL; the remainder is considered a contribution to exempt functions of the Association.)

INTEGRATING INCOME MAINTENANCE PROGRAMS

edited by IRENE LURIE

A Volume in the INSTITUTE FOR RESEARCH ON POVERTY MONOGRAPH Series

The result of a conference of academic and government experts held under the aegis of the Institute for Research on Poverty, the eleven papers in this volume can serve as a basic reference and guide to the nation's income support system, and will be fundamental in any effort to reform it. They analyze its deficiencies and examine ways of integrating its programs into a system that makes sense.

CONTENTS: *I. Lurie,* Integrating Income Maintenance Programs: Problems and Solutions. *L. J. Hausman,* Cumulative Tax Rates in Alternative Income Maintenance Systems. *B. A. Okner,* The Role of Demogrants as an Income Maintenance Alternative. *R. H. Haveman,* Earnings Supplementation as an Income Maintenance Strategy: Issues of Program Structure and Integration. *T. W. Mirer,* Alternative Approaches to Integrating Income Transfer Programs. *H. J. Aaron,* Alternative Ways to Increase Work Effort under Income Maintenance Systems. *M. Schmundt, E. Smolensky, and L. Stiefel,* When Do Recipients Value Transfers at Their Costs to Taxpayers? *M. K. Taussig,* The Social Security Retirement Program and Welfare Reform. *R. Munts,* Programming Income Maintenance: The Place of Unemployment Insurance. *T. R. Marmor,* Public Medical Programs and Cash Assistance: The Problems of Program Integration. *M. Krashinsky,* Day Care and Welfare. *I. Lurie,* Rationales for Interstate Differentials in Assistance Benefits and for State Supplementation.

1975, 400 pp., $17.50/£8.40

SIMULATING THE URBAN ECONOMY

by P. SMITH and W. I. MORRISON

No. 7 of MONOGRAPHS IN SPATIAL AND ENVIRONMENTAL SYSTEMS ANALYSIS

Although the use of input-output analysis is increasing rapidly, the obstacle presented by the cost in time and money of obtaining survey data acts as a hindrance to even greater application of the method. The possibilities offered by nonsurvey methods are consequently very important.

In this book the authors have applied the methods developed by a number of workers to data derived from the 1968 UK input-output tables, and they have then compared the results with empirically obtained data for the city of Peterborough for the same year. This critical comparison of previous methods for the production of nonsurvey tables is accompanied by a number of the authors' own modifications to the methods, which demonstrate that significant improvements can be made in the estimates. In particular an iterative approach is described which incorporates sectoral estimates of local intermediate inputs and outputs, and makes possible the widespread simulation of regional economic systems.

1975, 152 pp., $10.50/£4.00

Published by PION LTD. Distributed by Academic Press.

BOUNDARY CONDITIONS AND GLOBAL MANAGEMENT

by GUIDO LOERO

On the basis of an analysis of a wide variety of economic, political, sociological, and psychological data and theories the author sees the conditions of modern life as pushing society towards major new resolutions of its problems, based on a broader viewpoint than that of mere economic efficiency. With particular attention to the role and problems of management, he sketches the new patterns of management decision-making, new structures of goverment, and new cultural patterns of needs and values whose emergence will better enable society to meet the human needs of its members.

FOREIGN TRADE REGIMES AND ECONOMIC DEVELOPMENT

Jagdish N. Bhagwati and Anne O. Krueger, Editors

This ambitious research project sponsored by the National Bureau of Economic Research analyzes the phenomena of exchange control, liberalization, and economic development in less-developed countries. There will be ten volumes on individual countries plus a synthesis volume.

- **Volume I: Turkey.** Anne O. Krueger, Editor. cloth, $17.50; paper, $5.00
- **Volume II: Ghana.** J. Clark Leith, Editor $15.00
- **Volume III: Israel.** Michael Michaely $12.50
- **Volume IV: Egypt.** Bent Hansen and Karim Nashashibi $17.50
- **Volume V: Philippines.** Robert Baldwin $10.00

A Special Conference Series on Foreign Trade Regimes and Economic Development

HOUSING MARKETS AND RACIAL DISCRIMINATION
A Microeconomic Analysis

John F. Kain and John M. Quigley

Based on a sample of roughly 1200 St. Louis households, 34% of which were Negro households, this study permits extensive analyses on the behavior of blacks in the housing market, pointing up the distortions caused by racial discrimination.

Urban and Regional Studies, 3 $17.50

HUMAN CAPITAL
A Theoretical and Empirical Analysis, with Special Reference to Education
Second Edition

Gary S. Becker

In the three new essays in this updated volume a convenient formulation is provided for statistical estimation of the relation between the lag of earnings, rates of return to human capital, and the time spent in investing in human capital; a model of wealth maximization is developed that explains the decline of investments over time; and a new approach is presented to household behavior.

CALCUTTA * CENTRAL LIBRARY

DECEMBER 1975

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

- Published at George Banta Co., Inc., Menasha, Wisconsin.

- THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

Association membership dues for 1976, which include a subscription to both The *American Economic Review* and the *Journal of Economic Literature*, are as follows:

$25.00 for regular members with rank of assistant professor or lower, or with annual income of $12,000 or less;

$30.00 for regular members with rank of associate professor, or with annual income of $12,000 to $20,000;

$35.00 for regular members with rank of full professor, or with annual income above $20,000;

$12.50 for junior members (registered students). Certification must be submitted yearly.

Subscriptions (libraries, institutions, or firms) are $37.50 a year. Only subscriptions to both publications will be accepted. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

For foreign postage, add: PUAS countries, $2.10; all other countries and Canada, $2.50.

- Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, Rendigs Fels, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

- Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

The *American Economic Review* is owned, managed, and published by the American Economic Association, a nonprofit educational organization, located at 1313 21st Avenue So., Nashville, Davidson County, Tennessee 37212. The Managing Editor is Professor George H. Borts, *American Economic Review*, Brown University, Robinson Hall, Providence, R.I. 02912. During the preceding 12 months the average number of copies printed for each issue was 27,400, the average paid circulation, 24,752; the average free distribution, 327; the average number of copies distributed, 25,079. Corresponding figures for the last issue before filing: 27,500 total number copies printed; 25,642 total paid circulation; 327 free copies distributed; 25,969 total distributions.

The 1975 Report of the President's Council of Economic Advisors: A Radical Critique

By JAMES R. CROTTY AND LEONARD A. RAPPING*

Capitalism by its very nature is an exploitative system. During periods of recession and depression, however, the burdens of capitalism on working people are intensified and brought into stark relief. Economic and political inequality grows, poverty becomes more pervasive, working conditions deteriorate, work relations become more dictatorial, economic insecurity increases, and the condition of blacks and other minorities as well as that of women worsens. All of these injustices accompany the semidepression of 1974–75, which is the most severe economic crisis since the 1930's.

The Employment Act of 1946 is generally assumed to have affirmed the government's commitment to relatively low unemployment and to the maintenance of reasonable price stability.[1] Yet 1974 was a year in which the unemployment rate was high and grew rapidly toward year's end. By May of 1975, unemployment reached its highest level in almost thirty-five years. During the year 1974, real wages fell; real consumption was stagnant; and the United States was experiencing one of the worst peacetime inflations in its history. In light of these events, the 1975 Economic Report of the President is an exceptionally important document because it represents an official explanation of why the government has either refused or been unable to fulfill its alleged promise of 1946.

The Report contends that the economic problems of 1974 resulted from a decade-long series of mistaken macropolicies which, in conjunction with oil and food price complications, left the policy makers in 1973–74 with no reasonable choice other than to precipitate a serious recession. In other words, with better policy judgment and a little more luck, the necessity of severe economic retrenchment could have and should have been avoided. We, on the other hand, will argue that the current economic crisis is systemic in nature and that the macropolicies of the past decade were rational and perhaps unavoidable given the political-economic objectives and constraints facing the macropolicy authorities. In this review, therefore, we will offer an explanation of the key events of 1974 that differs from the one presented in the Report.

---

* Economics department, University of Massachusetts. This review was written in mid-summer of 1975. We have benefited from the helpful comments of Sam Bowles, Richard Edwards, Tom Riddell, and Helen Sootin Smith. We are especially indebted to Raford Boddy who helped develop many of the ideas presented here. We acknowledge the intellectual support of our colleagues in the Union for Radical Political Economics, but we caution the reader not to assume that there is general acceptance within URPE of the views expressed in this paper.

[1] The exact wording of the 1946 Act as well as the congressional debate before its passage makes clear that the government did not commit itself to *full* employment. The Act itself was ambiguous, calling for "maximum employment and purchasing power," subject to the condition that these vague objectives not jeopardize the maintenance of the existing system of "free competitive enterprise." And it was chosen instead of an alternative bill under which the government really was to guarantee "full employment" for persons able and willing to work.

I. The Report: Description Without Explanation

The Report argues that the recession of 1974 and the accompanying rise in unemployment were caused in the first instance by the restrictive macropolicies of 1973 and 1974. These policies were required, in the view of the Report, in order to fight the inflation and correct the economic distortions which existed in this period. The unusual importance attached to the fight against inflation as well as the severity of the restrictive policies undertaken to combat it are basically explained by the inflationary expectations and tendencies which had become embedded in the economy after more than eight years of consistent inflationary pressure. In the logic of the Report, therefore, whatever explains the pattern of inflation since 1965 is also the key to understanding the recession of 1974 and beyond.

The explanation of inflation offered in the chapter on inflation and throughout the Report focuses primarily on the role of macropolicy. The opening paragraph in this chapter instructs us as follows:

> Without neglecting specific features, the U.S. inflation since the mid-1960's can nevertheless be analyzed in terms of a general conception of the inflationary process that emphasizes the role of monetary and fiscal policies, *and the decision-making process that leads to these policies.* [p. 128] (emphasis added)

The explanation begins with the obvious proposition that inflation develops when aggregate demand exceeds aggregate supply and the less self-evident proposition that inflation is a cumulative process—the longer demand exceeds supply, the greater the inflationary pressure. The Report argues: "Any explanation of inflation must therefore come to grips with the question of why, about 1965, aggregate demand started to grow so much faster in nominal terms than real output, and why it has continued to grow at a faster rate subsequently" (p. 132). It argues further that the growth of demand was caused primarily by overexpansionary macropolicy. Since fiscal policy is assumed incapable of sustaining demand growth in the absence of accomodating monetary policy, the explanation reduces to an observation of the *fact* that "the Federal Reserve System did not prevent this sustained period of steepening inflation" or that "the regulation of the money supply has not prevented these undesireable price trends" (pp. 133 and 134).

The Report never really tells us why the Federal Reserve permitted this decade of inflation. The monetary authorities were hardly unaware of the problem. In fact, the Report notes that the Federal Reserve did tighten policy on three occasions during this period—1966–67, 1969–70, and 1973–74. It asserts, however, that certain "pressures" were placed on the monetary authorities to return to expansionary policies. These pressures are said to have become increasingly strong in late 1974, but their source is not identified precisely. One motive suggested is " . . . the effort of [monetary] policy makers to play safe against recessions or at least to postpone them and to promote a very rapid rate of cyclical expansion in the advanced stages of the recovery after the recession of 1970" (pp. 135–36). Are we to imagine William McChesney Martin and Arthur Burns fighting at all costs to prevent recession, whatever the inflationary or balance of payments consequences? Surely the pressures on the Federal Reserve System in 1966–67 and 1970 were something other than or besides a simple abhorrence of unemployment.

In spite of the fact that the Report stresses that any explanation of the key events of 1974 and the inflation of the preceding decade must be based on an analysis of macropolicy and "the decision-making process that leads to these policies," it does not follow its own dictum. It presents no explicit theory of the macropolicy decision-making process. The Report never even clearly specifies a set of macropolicy objectives and constraints, let alone a political theory to be used as the analytical foundation for understanding the process of macropolicy decision making. Scattered throughout are a mélange of such policy objectives as price stability and income and employment maximization which are implicitly assumed to be in everyone's best interest. These objectives are normally associated with a relatively simple if not simplistic pluralist political theory. But such a theory is clearly inadequate for understanding the political realities of a capitalist system characterized by the existence of classes whose conflicts influence or dominate the political process. While it may pass muster in high school civics texts, naive pluralism won't do as a guide to a world in which giant corporations dominate the domestic and international economy, and where their owners and managers generally exercise decisive influence in political institutions and their supporting ideology envelops virtually all public political debate.[2] Lacking a realistic underlying theory of the state, therefore, the Report's explanation of the economic crisis finally turns out to be mechanical, superficial, and behaviorally empty. It must be judged inadequate under its own ground rules.

For the purpose of this review, we accept the Report's *description* of the events of 1974 and will focus on the question of *why* 1974 turned out to be an economic disaster. The reader should not expect a detailed critique of the Report nor a consideration of the numerous controversial technical issues which it raises. Rather, our discussion will center on broad questions concerning the underlying structure of the American economy, and the economic and political factors which explain the formation of monetary-fiscal policy. Consistent with the Report, we assume that the events of 1974 are only fully comprehensible when viewed as the culmination of an organic historical process.

We begin by sketching the essential components of a theory of macropolicy consistent with our understanding of Marxian social theory and a derivative theory of the state. This theory of policy is based on class and nation-state conflict and stresses contradictions in both the domestic and international economic systems. We then use this theory to interpret or explain important economic developments in the 1965–73 period that set the stage for the inflation and recession-depression of 1974–75. Finally, in the context of the current crisis, we speculate on the political-economic prospects for the rest of the decade.

II. The Foundation of a Theory of the Crisis

The history of American economic development since World War II and of the macropolicy of this era is best understood in terms of several fundamental conflicts. This analysis will stress two of these. Domestically, there exists a basic conflict between capital and labor which leads to a struggle over the division of the national product. Internationally, a fundamental conflict exists among the various capitalist nation-states over export markets, access to raw materials, control of foreign investment and—in a very general sense—each country's place in the hierarchy of international economic, political, and military relations. This competitive struggle takes place within a broader conflict between the third world underdeveloped nations and the developed capitalist nations. The presence of developed or developing countries outside the capitalist orbit constrains intercapitalist rivalry and offers alternatives to underdeveloped nations.

---

[2] We do not at all mean to suggest that the absence of an explicit, well-developed theory of policy or theory of political economy in the Report implies an equivalent absence of political sophistication or lack of ideological commitment in the Council members who wrote it. On the contrary, this year's Council is one of the most conservative in history. Alan Greenspan is a disciple of Ayn Rand and perhaps the most openly ideological Council chairman ever. The political sophistication of this or any Council should be judged not by the apparent quality of the political economy of the Report, but by the degree to which the Report accomplishes its real purpose: to justify, not critically analyze, the policies of the Administration; to explain away, rather than explain, the economic problems of the period; and to praise, not question, capitalism as an economic system. The political and ideological bent of the Council will be determined by the basic policy thrust of a particular administration. For example, a conservative Council headed by Greenspan seems ideally suited for purging the economy of inflationary excesses by means of a severe recession-depression.

A. *Class Conflict and Macropolicy*

While it is undoubtedly true that the working class has achieved important political victories in modern American history, the process of macropolicy formulation in the post-World War II era has been dominated by the interests of the capitalist class.[3] Organized labor has represented a constraint limiting the policy choices available to capital, but by no means has it been an equal partner in the formation of macropolicy. The main objective of policy has been to protect and extend corporate profits. John Gurley expressed this point well in this *Review:*

> The ultimate and overriding objective of all capitalist governments is the preservation and strengthening of capitalism—that is, of the private enterprise system. In our own economy, this means that successive Administrations, above all else, have looked out for the welfare of . . . the few hundred industrial, commercial, and financial giants that define and shape the U.S. economy. Since the welfare of these huge corporations is best measured by their profits, the basic concern of U.S. Administrations has been the protection and promotion of these corporate profits . . . [F]ull employment, welfare programs, and price stability, are, in the final analysis, judged by the extent to which they are compatible with private profit making. [p. 20]

Capital's control of macropolicy and its quest for maximum corporate profits would be a secondary issue were the impact of policy always class-neutral. The 1975 Report implicitly assumes, as did its predecessors, that policy choices exist that are optimal for both capital and labor. In particular, this harmonious view assumes that labor's key objective, sustained full employment, and capital's objective, maximum profits, are compatible.[4] According to this reasoning, reaching the twin objectives of full employment and maximum profits involves mainly technical problems, and it is assumed that the basic structure of the economy is consistent with the simultaneous achievement of both goals. Neoclassical and Keynesian theorists lent considerable support to this view because they implicitly and erroneously assumed that the unique conjunction of historical events after World War II, which facilitated worldwide capitalist expansion and growth under American tutelage, would last forever. And the Employment Act of

---

[3] Supporting the important assertion that capital controls macropolicy formation would take us beyond the scope of this paper. We have little doubt, however, that policy makers are both sociologically and ideologically more closely tied to capital than labor. Moreover, the dominance of capital in the policy formation process is clear to us from our reading of the historical "case studies" reported by those who have examined macropolicy formation. The best and most informative of these studies has been done by Herbert Stein. For an analysis and some empirical tests of the proposition that capital dominates macropolicy formation, see Crotty.

[4] Within the constraints of *existing* institutions or relations of production some policy objectives, such as the avoidance of economic collapse, are in the interests of both classes. The reader who questions the primacy of the job issue in the objectives of organized labor should consult the trade union literature and AFL-CIO policy positions during every recessionary period.

1946 seemed to commit the state to balanced full employment growth while Keynesian theory indicated that it could be achieved.

In the final chapter of the *General Theory*, Keynes declared that capitalism had but one major problem which could be permanently resolved through sensible government policy. That problem of course was that aggregate demand tended to fall short of aggregate supply at full employment leading to recessions or depressions which were not self-correcting. He wrote:

> If our central controls succeed in establishing an aggregate volume of output corresponding to full employment . . . , then there is no objection to be raised against the classical analysis of the manner in which private self-interest will determine what in particular is produced, in what proportions the factors of production will be combined to produce it, and how the value of the final product will be distributed between them. [pp. 378–79]

Keynes' key assumption is that the market system coordinating firm with firm, sector with sector, and factor with factor, works reasonably well and quickly when the government sets aggregate demand at the level consistent with full employment. In other words, the market system can handle all the tasks of micro-balancing. Moreover, once government provides full employment through macropolicy, the international sector is no longer an overriding policy constraint: "If nations can learn to provide themselves with full employment by their domestic policy . . . there would no longer be a pressing motive why one country need force its wares on another or repulse the offerings of its neighbor . . . with the express object of upsetting the equilibrium of payments so as to develop a balance of trade in its own favor" (p. 382).

An alternative to the Keynesian view of macropolicy, one based on capital-labor conflict, maintains that the basic structure of the economy precludes the simultaneous attainment of labor's and capital's objectives. The existence of a conflict between full employment and profit maximization is supported by empirical evidence from the past twenty-five years. The typical pattern of the post-World War II business cycle shows that the profit share of income and even the absolute level of real profits have fallen in the latter phase of the expansion. This full employment profit squeeze helps explain both the failure of capitalist-oriented macropolicy to sustain full employment prior to 1965 and the consequences of full employment during the Vietnam War period of the late 1960's.

The primary problems with sustained full employment from the perspective of the capitalist class are that it creates conditions which lead to the continuous decline of profits and profit margins, to an increase in labor's share of national product, to domestic financial instability, and to the erosion of the international financial institutions through which the American empire was developed and is maintained. Intermittent recessions are a necessary condition for the maintenance of satisfactory profits and the health of financial institutions. The tradeoff between profits and full employment enables the state to partially mediate this capital-labor conflict through macropolicy. Control of the policy-making apparatus therefore becomes central in determining the influence of macropolicy on the outcome of this conflict. The state cannot be expected to pursue full employment since those who formulate macropolicy are primarily concerned with the welfare of capital and the preservation of capitalist institutions.

B. *Profits, Wages, Productivity, and the Cycle*

In the absence of wage-price controls,

full employment and high profits are incompatible. This contradiction is a cornerstone of Marxian business cycle theory.[5] Consider the economy emerging from a recession and entering the early phase of an expansion. Wages are rising moderately, but productivity growth is very rapid, so that stable or moderately rising prices yield increasing profits and profit margins. Capacity utilization is rising but is not yet so high that shortages develop. Credit is cheap and readily available, but credit demand is moderate because cash flow is sufficient to accommodate most business needs. Investment is rising, business and consumer confidence is strong, and the stock market is buoyant. Trade and payments accounts are improving. Employment is growing and with a lag the rate of unemployment begins to decline from its recession highs.

When relatively full employment is approached, however, a series of distortions develop which, in Wesley Mitchell's words, "cause a slow accumulation of stresses within the balanced system of business . . . that ultimately undermine the conditions on which prosperity rests" (quoted in Geoffrey H. Moore, p. 7). For Marx, the most important of these stresses derives from the continuous conflict of capital and labor over wages and the conditions of work. Marx argued that the division of national product depended in part on class struggle. Capital-labor conflict over wage and profit shares, coupled with the relentless drive for capital accumulation, produced, according to Marx, cyclical booms and busts.

The reduction of the reserve army of the unemployed which accompanies the expansion, strengthens the bargaining position of the working class in its labor market confrontation with capital. Workers can then struggle successfully for higher wages. In the latter part of the expansion, moreover, the rate of increase in productivity decreases and consequently unit labor costs rise rapidly. While the growth in unit labor costs drives corporations toward labor saving capital equipment, the resulting productivity gains are only realized in the early phase of the next expansion when the new capital is actually installed. Although developing "technical" bottlenecks and inefficiencies partially explain the productivity slowdown, knowledgeable observers of the labor scene have pointed directly to an increasingly obstreperous labor force as an explanatory factor. Full employment affects not only wage rates, but also quit rates, strikes, and labor militancy in general.[6] It has been a longstanding observation that such favorable conditions for labor evoke less effort on the shop floor.[7] For example, a plant superintendent testifying before the Commission on Labor in 1904 had the following to say:

> Five years ago men did not restrict their output, union or non-union men, because they wanted to hold their jobs and a man would do anything and all he was told to do. Now a man knows that all he has to do is to walk across the street and get another job at the same pay. During the hard times we took contracts at any price we could get, and in some places and cases men were driven at high speed to get this work out, so as to lose as little money on it as possible. Men will not keep up that speed rate in these days. [as quoted in Mitchell, p. 113]

In this phase of the expansion, inflation accelerates, but not enough to prevent profit margins from deteriorating. Although there is no unique and universally accepted hypothesis that explains why prices do not keep up with costs, the fact that they do not is of extreme importance. For profits and profit margins end up being squeezed toward the top of the boom. The termination of the expansion and the rebuilding of the reserve army is required to relax this profit squeeze. As Marx put it:

---

[5] A fuller discussion of the propositions contained in this section can be found in Raford Boddy and Crotty (1975a).

[6] For evidence on the relationship between labor market conditions and strike activity, see Douglas Hibbs.

[7] In Marxian economics a useful distinction is made between labor and labor power. The distinction is explored in a recent review of human capital theory by Samuel Bowles and Herbert Gintis.

> If the quantity of unpaid labor supplied by the working class, and accumulated by the capitalist class, increases so rapidly that its conversion into capital requires an extraordinary addition of paid labor, then wages rise, and, all other circumstances remaining equal, the unpaid labor diminishes in proportion. But as soon as the diminution touches the point at which the surplus labor that nourishes capital is no longer supplied in normal quantity, a reaction sets in: a smaller part of revenue is capitalized, accumulation lags, and the movement of rise in wages receives a check. The rise of wages therefore is confined within limits that not only leave intact the foundations of the capitalist system, but also secure its reproduction on a progressive scale. [p. 620]

Empirical evidence from the post-World War II era supports the hypothesis that there is indeed a full employment profit squeeze.[8] Profits tend to peak, both in relative and absolute terms, approximately halfway through the typical expansion. Profitability is eroded during the latter part of this phase as labor markets tighten and continues to decline during the contraction. This pattern is discernable in each of the post-World War II cycles. However, the expansion of the 1960's is the only one in which there was prolonged full employment. It therefore provides us with the best opportunity to test the full employment profit squeeze hypothesis. The evidence of this period dramatically supports the hypothesis, whether profitability is measured as a share, as a rate of return, or in dollars. Net profits before taxes as a percent of gross product originating in nonfinancial corporations rose steadily from 14.5 in 1961 to a peak of 17.0 in 1965, then fell steadily to a postwar low of 9.8 by 1970. Compensation of employees, on the other hand, declined from 65.1 percent in 1961 to 62.6 in 1965, rising thereafter to 65.1 in 1969 and 67.2 in 1970. As reported by Nordhaus, the rate of return on nonfinancial corporate capital rose from 11.8 percent (before taxes) in 1961 to 16.3 percent in 1965; it then fell steadily to a post-World War II low of 9.1 percent in 1970. Before tax corporate profits for all industries in current dollars rose from $50.3 billion to $82.4 billion between 1961 and 1966. They were $79.8 billion and $69.2 billion in 1969 and 1970, respectively. In real terms, they declined steadily and strongly from 1966 through 1970.

The full employment squeeze on profits means that continuous expansion would undermine the accumulation of profits. It is the profit squeeze, not inflation per se, which motivates capitalists to eventually demand restrictive macropolicies during periods of full employment.[9] The fact that profits are lowest in recession has often been used to argue the preposterousness of the charge that recessions are desired by capital. Indeed they would prefer to avoid them. But the recession is a necessary condition for establishing the basis of the highly profitable first phase of the expansion and for avoiding the highly unprofitable consequences of sustained full employment. Recessions also provide the political context within which the government grants fiscal incentives to capital. Under the impact of recession-induced corporate tax reductions, the post-World War II period has witnessed a secular decline in effective corporate tax rates.

---

[8] Evidence in support of the full employment profit squeeze hypothesis may be found in Boddy and Crotty (1975a), Albert Burger, Thor Hultgren, and William Nordhaus.

[9] Michał Kalecki in his seminal 1943 paper argued that periodic recessions were essential to the maintenance of capitalist institutions. He stated that "... under a regime of permanent full employment, the 'sack' would cease to play its role as a disciplinary measure." For Kalecki it was not the conflict between high profits and full employment that necessitated recessions, but rather the fact that full employment would undermine "discipline in the factory" and that the "class-consciousness of the working class would grow."

Of course other problems also develop during the expansion. The deterioration of profitability in the latter phase of the expansion means that corporations turn increasingly to external sources to finance investment in plant, equipment, and inventories. Rising prices and the fear of shortages accelerate inventory accumulation, while inventory profits and depreciation at historical costs increase the effective tax rate on corporate profits. Debt accumulates just when interest rates are highest. Moreover, serious balance of trade problems develop as the rising price of *U.S.* products retards exports and, aided by strong aggregate *U.S.* demand, stimulates imports.

Eventually of course lower profits and associated stresses restrain production and investment and thus, before long, the expansion tends to abort. Macropolicy can work by either acquiescing in this tendency toward contraction or can extend the expansion for months or even years beyond its "natural" life. In the 1945–65 period, the government reacted to the decline in profits, the rise in inflation, and the problems in the international sector as we would expect—by reinforcing the recessionary pressures developing in the private sector.

The economic function of recession in a capitalist economy is to create the preconditions for a new expansion of profits. By taking away the jobs of millions of people, and by threatening the jobs of millions of others, recessions reduce worker demands. Unit labor costs are brought under control, the decline in profit margins is eventually stopped, and inflationary pressure weakens. During recessions inventories are cut, loans are repaid, corporate liquidity positions are improved, and the deterioration in the balance of payments is reversed. All the statements of Keynesian economists to the contrary notwithstanding, recessions are inevitable in the unplanned economy of the United States because they perform an essential function for which no adequate substitute has thus far been available.

C. *World Capitalism, U.S. Hegemony, and Macropolicy*

The preceding analysis assumes that when capital controls the process of macropolicy making, the primary concern of policy is the profitability of major corporations. However, corporate profits—domestic as well as foreign—are fundamentally dependent upon the condition of the international economy and the relative position of the United States therein. The state, therefore, must formulate macropolicies which support and sustain world capitalism as a system, and, simultaneously, attempt to maximize the strength of the United States vis-à-vis its capitalist rivals. Pursuit of these two international objectives sometimes leads to serious policy contradictions.

Relations among independent, capitalist nation-states generally reflect both the harmony of interest binding together the fortunes of these states and the much more important intercapitalist rivalries inherent in these relations. This harmony-conflict dialectic manifests itself in every historical period. The periods of international harmony are usually those in which one dominant nation-state orders intercapitalist relations and suppresses conflict. International stability as we have known it seems to require a single hegemonic state.[10]

---

[10] This view is common in the Marxist literature, but for the reader who finds this literature unbecoming, the

It is the function of the dominant state to provide reasonably unfettered access to its markets, to provide credit, to maintain free trade, and to assure a liberal flow of capital and aid. For a world in which powerful noncapitalist states exist and in which third world revolutionary forces are increasingly insistent on a change in the social relations of production, the dominant capitalist state must also provide the military and political might and leadership to contain socialism and to prevent revolution. Without a dominant power the exchange relations of the capitalist world are basically unstable and break out in destructive, competitive rivalries. Trade wars, rising tariffs, import quotas, exchange controls, and barter arrangements are among the more important manifestations of disintegrating international exchange relations. The collapse of trade and credit relations in the 1930's and the uncertainties of the 1970's are two important historical examples of the instability of the world economy in the absence of a dominant state. Indeed, the Report expresses surprise and relief that protectionism was not more virulent in 1974.

The basis for stability in the postwar international system prior to August of 1971 was American political, economic, and military dominance. Within the framework of the Bretton Woods agreement, exchange rates were stabilized and the dollar served as both an international money and a reserve currency. Markets for both goods and direct investments as well as sources of cheap raw materials were protected and expanded by American military and economic assistance, which was provided directly as well as indirectly through American-dominated international agencies. Third world revolutionary forces were suppressed or contained by the unrelenting activities of *U.S.* agencies such as the Pentagon, the CIA, and the AID.

It is crucial to understand that the relative stability and prosperity of the *U.S.* economy in the period from 1946 to 1969 was based on the stability and order of the international capitalist system and the paramount position of the United States in that system. Foreign profits of *U.S.* corporations rose steadily throughout the period, both absolutely and as a percent of total corporate profits. The United States was guaranteed a supply of cheap raw materials and it gained control of an increasing proportion of world oil supplies. The entire nonsocialist world was kept "open" for *U.S.* trade and foreign investment. The policies of third world countries in particular were shaped so as to maximize the profitability and safety of *U.S.* interests. Exchange rates were not only kept stable, but the *U.S.* dollar was increasingly overvalued as time went on, providing cheap imports and facilitating the accumulation of foreign capital assets. The reserve position of the dollar not only meant that the economy was insulated from retrenchment shocks required by short-run balance-of-payments problems, but that the United States could finance much of its overseas military, economic, and political activities by printing dollars.[11] In general, the ability of the United States to control its international environment to a greater degree than in any other period in its history created international stability in the context of American dominance which was the sine qua non of the relative domestic sta-

---

recent book by Charles P. Kindleberger on the Great Depression will be enlightening. Kindleberger prefers to use the term leadership rather than hegemony, but regardless of terminology, the point is that stability in the international capitalist system requires an enforcer.

[11] Between 1950 and 1973, the United States directly exported (net) $96 billion of long-term capital and expended $73 billion on military and economic aid. Of this total, $78 billion was financed by earnings on the export of goods and services, while $91 billion was financed by short-term capital and gold flows. (Source: Landsberg, Table 1.) For a fuller discussion of this process, see Paul Sweezy and Harry Magdoff.

bility and the prosperity of this era. The economic chaos of 1974 is in large part the result of the end of the total dominance of the United States and the international disorder which accompanied it.

Post-World War II international stability facilitated world capitalist integration and unprecedented economic growth, as witnessed by increasing world trade, extensive direct investments, and the rise of the multinational corporation. By pre-1939 standards the separate economies of the Western capitalist countries and Japan also experienced substantial growth and stability. But this system was destined to self-destruct. The growing strength of the European Economic Community and Japan greatly increased world capitalist competition, undermining the basis of international order—*U.S.* hegemony. And the increasing strength of third world revolutionary forces eventually led to the American defeat in Southeast Asia, a major historical event that further eroded *U.S.* control. Finally, a cornerstone of stability collapsed in August of 1971 when the Bretton Woods system came to an end.[12] The power vacuum created by these developments has yet to be filled.

Pressures on macropolicy emanating from the international sector can be placed in two general categories: 1) the "normal" month-to-month and year-to-year dynamics of trade, investment, and financial capital flows; and 2) the inevitable wars and lesser military skirmishes which arise as a natural result of the United States' role as capitalist policemen of the third world and defender of the international capitalist system against the encroachment of socialism. Between 1945 and 1965 there existed a rough correspondence between domestic macropolicy requirements and the requirements of the international system. The behavior of the economy over the cycle generates simultaneous pressures to relax the economy for both domestic and "normal" international objectives. The refusal of the macropolicy authorities to follow expansionary policies during the recession of 1957–59 is an important historical example of this coincidence of objectives. There is, of course, no systematic reason to expect the changes in military expenditures necessitated by *U.S.* international objectives to coincide with domestic economic needs. Yet, the military expenditures on World War II and on the Korean War did help to revive a sagging economy.

The first dramatic conflict among these policy objectives occurred in 1965. Late that year, as 4 percent unemployment was attained, profit margins peaked and the trade surplus began to deteriorate. Both domestic and normal international interests required a recession and the Council of Economic Advisers called for more restrictive policies.[13] The Johnson Administration, however, with the approval and support of corporation owners and managers, had already made the fateful judgment that a military victory over the revolutionary forces in Vietnam was essential to the maintenance of the world capitalist system and the protection of the American place in it.

III. Working Out the Contradictions: 1965–74

Having sketched the foundations of a theory of the crisis, we now use these ideas to interpret and explain the important economic developments beginning in the critical year 1965 that set the stage for the inflation and recession-depression of 1974–75.

---

[12] For a more complete exposition and analysis of the events which ended *U.S.* dominance, see the interesting paper by Arthur MacEwan.

[13] Arthur Okun, then member of the Council of Economic Advisors, states that: "the President was told by his economic advisers at the end of 1965 that a general increase in income taxes was desirable to avoid excess demand" (p. 70).

A. *The Period 1965–71*

The administration's decision to escalate the war was a momentous gamble. Unless the government compensated for the sharp rise in military expenditures with either increased taxes or greatly reduced domestic spending, the war-related expenditures would eventually generate domestic economic instability, would place a severe strain on international financial institutions, and would jeopardize the special status of the United States in the world capitalist system. But the administration was constrained. It was unable to reduce domestic spending because of explosive unrest in the black urban areas, and it was unwilling to raise taxes because of fear that this would fuel incipient political opposition to war policies.[14] Except for the delayed and ineffective tax surcharge of 1968, the Johnson Administration chose to let inflationary war finance run its course. The Federal Reserve, on its part, started to squeeze money markets in late 1966 in an attempt to reduce demand pressures. But they almost initiated a financial collapse in the process and relented under pressure from the corporate sector.

The gamble failed. Yet the fact that it was undertaken, given the enormous political-economic costs involved, indicates how important the defense of the empire was to the policy makers. No other single event speaks so eloquently and convincingly in support of the hypothesis that the international interests of *U.S.* corporations are of paramount importance in the objective function of macropolicy authorities.

By the end of 1968 the costs of the Vietnam War had become obvious. The domestic economy had been severely strained by long years of expansion and dangerous pressures were building on the world payments system. Profit margins were low, labor's share was growing, interest rates were high, inflation was accelerating, and the *U.S.* balance-of-payments position was deteriorating. Certainly it must have appeared that a recession lasting as long as three or four years would be required to curb the pressures and end the dislocations generated by eight years of continuous expansion and five years of continuous tight labor markets. In 1969, the incoming administration began to deal with these problems by means of classic recessionary policy.

The actual recession of 1969–70 was rather short, lasting only five or six quarters. Restrictive macropolicy was eased in 1970 because profits, squeezed first by five years of tight labor markets and then by the initial impact of the recession, were in need of immediate relief; because its continuation would have led to a rate of unemployment so high that it could not possibly have been reduced to a politically acceptable level in time for the 1972 presidential election; and because the debt and liquidity structure of many corporations and banks raised questions as to whether they could survive the usual recessionary medicine.[15] As a result of recessed business conditions and less restrictive monetary policy in 1970, interest rates dropped by almost 60 percent by early 1971. This massive drop in *U.S.* short-term interest rates triggered equally massive short-term capital outflows. These outflows were combined with a trade balance which was being progressively eroded by inflation, demand-induced import growth, and Common Market tariff policies restricting *U.S.* agricultural exports. The outcome was a veritable explosion in the *U.S.* balance-of-payments deficit. By August 1971 this flood of *U.S.* dollars created such pressure on the international monetary system that an immediate response by the administration was essential.

---

[14] Evidence in support of this position is contained in a recent unpublished study by Thomas Riddell.

[15] That the financial condition of large corporations limits the use of restrictive monetary policy is understood by many knowledgeable observers of the economic scene. In a recent book, Leonard Silk, for example, asserts that "[the] liquidity squeeze . . . seemed to be threatening some businesses with financial disaster. . . . " He goes on to say: "The Federal Reserve's tight money policies during the latter part of 1969 were clearly involved in the liquidity squeeze. Chairman Burns . . . , facing a potential monetary panic, now threw Friedmanism to the winds and began to pour money into the economy. During the year following the near panic of May, 1970, M_1 grew by 8.5 percent and M_2 by 13 percent . . . " (p. 12).

B. *The Legacy of 1965–71*

The macropolicy decisions taken in support of the prosecution of the Vietnam War prolonged the American economic expansion through 1969—three or four years beyond its "natural" life. This extended expansion, culminating in five years of relatively full employment, had a number of significant effects on macrotheory and macropolicy.

It destroyed the credibility and general acceptance of the Keynesian promise of full employment, and it exposed the instability of the economic system. It eventually led to the imposition of government controls, signalling the end of the Keynesian "revolution." Whatever function macro-demand management may play in the future, the idea that the economy can be satisfactorily guided through Keynesian policies alone was permanently interred.

The domestic legacy of these years included a disproportionate buildup of personal and corporate debt, brought on in the corporate case by a sustained high level of investment and inventory spending undertaken in the context of declining profits and cash flow. Corporations were increasingly pushed to debt financing. In turn, the rise in indebtedness increased the tendency of the economy to develop liquidity crises and credit crunches. Put differently, it reduced the tolerance of the system for recession while increasing the necessity of a recession-induced reliquidation of the economy. In addition, the economy carried over both high rates of inflation and strong inflationary expectations.

The policies of the Vietnam period hastened the decline of the American monopoly of international capitalist power, consequently destroying the basis on which international stability rested. The unprecedented length of the *U.S.* expansion created an environment in which the export-oriented economies of Europe and Japan could sustain their own derivative expansions and accelerate their assault on our balance-of-trade surplus and our share of world export markets. The decade-long expansion in the world capitalist system in turn laid the foundation for a worldwide raw material or commodity inflation. In concert with the declining ability of the United States to control world events, the world commodity boom created the necessary preconditions for the coming economic and political revolt of the third world producers of raw materials, most significantly that of the oil-exporting countries. The balance-of-payments deficits and inflation-exportation of this period clearly hastened the demise of the existing international economic and financial institutions leaving little hope, in the power vacuum that existed, for a set of substitute institutions and arrangements.

In short, the expansive macropolicies chosen in the late 1960's to accommodate the defense of *U.S.* hegemony in the end accelerated its demise, leaving by August 1971 a legacy of international instability and an unmet need for a prolonged recession in a domestic system that seemed incapable of easily surviving one. It is thus clear why the administration was forced to abandon exclusive reliance on orthodox macropolicy. On the one hand, the system needed expansionary macropolicy to stimulate short-run profits and investment and to keep unemployment from rising too high. On the other hand, it needed restrictive policy to curb inflation, kick interest rates back up, improve the trade balance, and get labor fully under control. By August 1971 there was simply no combination of standard macropolicy tools capable of achieving these contradictory objectives. Nor could macropolicy deal with Europe's intransigence on the agricultural export question. The emergency in the international monetary system—a cornerstone of *U.S.* international hegemony—would not permit a delay in action. The administration's response was the New Economic Policy (*NEP*).

C. *The NEP and the Oil Crises: Setting the Stage for 1974*

We have argued that in order to explain the events of 1974 it is necessary to establish the position of the economy at the beginning of the year and evaluate the vector of forces affecting it. Specifically, the decision of the macropolicy makers to precipitate a semidepression is only comprehensible in light of such phenomena as rampant inflation, severe corporate financial stress, shortages amid massive inventory speculation, continued deterioration of the American international position, heightened international financial instastability, and the oil crisis. These forces posed the most serious threat to American capitalism since the 1930's. Analytically, then, the question at issue is why the economy was under more severe stress at the end of the *NEP* than it was in 1971 when the *NEP* was initiated.

The *NEP* was designed to achieve a set of objectives which were deemed contradictory in the absence of wage-price controls. Its proximate cause was the debacle in the international sector and, in our opinion, its chief objective was to rebuild the *U.S.* international position. Domestically, the *NEP* was intended to provide the framework within which orthodox macropolicy could generate an expansion which would both revive profits from their depressed level and prevent excessive inflation. The two objectives were obviously interrelated since control of domestic costs was essential to the rebuilding of international economic strength.

Most aspects of the international rationale for the *NEP* are clear. But the strategy of the "great agricultural export drive" has received little attention and merits discussion, particularly since the Report's chapter on food and agriculture fails to directly acknowledge the government's own contribution to food price inflation. The short- to medium-term strategy for protecting *U.S.* international interests was pretty well determined by the spring of 1971. A large trade surplus was considered essential for the financing of government spending and corporate investment abroad, and for providing a margin of safety against short-term capital flows. Secretary of the Treasury Connally stated that the trade balance had to move from a $4 billion deficit to a $9 billion surplus—a $13 billion turnaround. Agriculture was the only trade category which could be increased enough to cover a significant part of the requirement. In 1971 the Nixon Administration adopted an agricultural export policy to recoup its international losses.[16]

---

[16] The argument on the agricultural export drive referred to in this section is more fully developed in Boddy and Crotty (1975b). Their study analyzes the report and recommendations of the influential President's Commission on International Trade and Investment Policy. The Comission's report was formally presented to Nixon in July of 1971, although he was briefed on its contents at least as early as April of that year. The Commission's recommendations in support of the agricultural export drive and other international objectives later became the *NEP*. In the words of historian Joyce Kolko, the

The *NEP* was an integral part of this policy. On the demand side, the *NEP* contained two key provisions. The dollar devaluation was designed to make *U.S.* agricultural exports more competitive on world markets. The import surcharge represented an attempt to coerce Europe into negotiating a new agricultural trade policy to replace the Common Agricultural Policy (*CAP*), which had, since the middle 1960's, virtually excluded large scale American grain exports. The existence of an *EEC* import barrier in the context of a *U.S.* agricultural export drive explains the seemingly irrational decision of the administration to permit the massive sale of grains to the Soviet Union at subsidized prices.

The strategy on the supply side was somewhat more complex and intimately involved wage-price controls. By partially restraining price increases on those industrial goods which are agribusiness inputs, controls held down the cost of agricultural output. Farm products at first point of sale were specifically exempted from price controls. Agribusiness was thus assured of rising profit margins which, when combined with the removal of acreage restrictions, ensured a dramatic increase in production. Channelling this production into the export sector was accomplished in two ways. First, the combination of controlled wages and rising food prices meant that American workers could not afford their historic share of domestic agricultural production. Second, the lion's share of production would move to the export sector where prices were uncontrolled, while domestic food processors and retailers were subject to restrictions on the pass-through of cost increases. Higher profit margins could thus be obtained in the export sector.

The export drive was successful. The value of food exports in fiscal 1972 was $8.0 billion; by fiscal 1974 it had increased to $21.3 billion. Though the degree of success was dependent upon a series of crop failures around the world, a huge increase in agricultural exports was assured by the mechanics of the *NEP*, as was a maximal response to any unforeseen increase in world demand. The Report tells us that "every incremental increase in [agricultural] tonnage shipped . . . represents a corresponding reduction in the supply available to the domestic economy—and an increase in prices to the domestic economy" (pp. 183–84). One can only conclude that food price inflation was built into the *NEP* as a foreseeable and unavoidable consequence.

It is evident therefore that the *NEP* as a total package, including wage-price controls, was designed to deal with the short-term aspects of the international crisis largely via the "great agricultural export drive." In fact, there was no major facet of the *NEP* which did not support, directly or indirectly, the American effort to strengthen its international hand. In this context one can view the attempt to reassert control over domestic costs and prices as a dramatic statement to international competitors that the United States was determined to put its house in order. After years of deterioration the United States was attempting to regain its dominance in the world capitalist system, including the retention of reserve currency status for a strengthened dollar in a realigned fixed-rate system.

The manner in which the *NEP* handled the domestic problem of rising prices and shrinking profit margins through wage-price controls is also generally well understood, but several points relevant to an

---

Commission "advised a temporary import surcharge, a change of currency parities, wage and price controls, negotiations to eliminate trade barriers—in short, outlined Nixon's August 15, 1971 speech overturning the existing international monetary system" (p. 15).

explanation of economic conditions in 1974 need emphasis.

We agree with the Report's tentative conclusion that controls did not eliminate inflationary pressure, but rather postponed it from 1971–72 to 1974. Controls permitted the application of expansionary fiscal and monetary policy in 1972 and early 1973. This expansion would not have been possible without controls. The expansion in turn created pressures which the partial control system was incapable of withstanding. The inflationary thrust of the system remained when the control apparatus was disbanded in stages. There was a steep secular trend of inflation in early 1974 and a price-wage bulge following the removal of controls on April 30th of that year. Moreover, controls eventually led to surpluses and shortages because they suppressed market forces which, however socially irrational with respect to any reasonable list of national priorities, are a necessary tool of resource allocation in our system. One common source of domestic shortages was the increased allocation of various commodities to the export sector where profits were relatively high. And current shortages led to the fear of future shortages and thus to the kind of speculative and inflationary inventory buildups that plagued the economy in 1974. In addition, of course, the devaluations of the *NEP* contributed substantially to the rise in the rate of inflation.

Thus, controls did not in the end permit macropolicy to expand the economy in a noninflationary way. The rate of inflation in 1972 and 1973 was probably lower than it otherwise would have been given the macropolicy of this period. But the existence of controls was a necessary condition for the existence of very expansionary macropolicy so that it is misleading to take the policy stance as given.

Given the historical relation between real wages and the business cycle, the extended decline in real wages beginning in January 1973 is notable. From December 1972 to December 1973, the *CPI* rose by 8.8 percent while average hourly earnings in the private nonfarm sector were held to a 6.7 percent rate of growth. Real hourly earnings in the private nonagricultural sector, adjusted for interindustry employment shifts and in manufacturing for overtime, after rising 2.8 percent in 1972 (December to December), fell by 2.3 percent in 1973 and at a rate in excess of 5 percent in the first four months of 1974. Based on our reading of the evidence, it seems reasonable to conclude that the controls as applied in 1973 and early 1974 contributed to the decline in real wages and, consequently helped maintain the level and share of profits.[17] Tighter restrictions on real wages would have aborted the expansion earlier by further restricting consumption spending. Yet, the contribution of wage controls to the maintenance of profit and cash-flow margins was insufficient to avoid exacerbation of corporate debt and liquidity problems.

The expansion of 1972 and 1973 was accompanied and largely supported by an enormous expansion of corporate and consumer debt.[18] Nonfinancial and financial corporations entered 1974 with far worse liquidity and debt conditions than at the end of the expansion of the 1960's. In spite of the fact that profits in 1972–73 rose considerably from the 1970–71 lows, the financial structure of corporate America was in a precarious situation unprecedented in the post-World War II era. Internal sources of funds—though growing—fell increasingly short of investment and inventory accumulation in 1972 and especially 1973. An increasing proportion of corporate borrowing was short term, and corporate liquid assets as a percent of short-term debt declined precipitously. Common stock offerings of manufacturing companies declined to negligible levels by the second half of 1973. The *NEP* expansion was debt-fueled to a greater extent than any of its postwar predecessors.

---

[17] It has been argued by Franco Modigliani and others that real wages in 1973 were not restricted by the controls. The evidence used to support the argument is that the movement of nominal wages in this period ***given the actual price pattern*** was consistent with nominal wage equations estimated with pre-*NEP* data. We draw exactly the opposite conclusion from the same evidence. The dramatic rise of food prices and the *CPI* starting in January of 1973 must have affected actual price expectations almost instantaneously, whereas the wage equations of pre-1971 vintage assume that a substantial time lag exists between a change in the price level and the incorporation of that change into price expectations and thus into nominal wage changes. That nominal wages adjusted as slowly to the galloping inflation of 1973 and early 1974 as they did to the creeping inflation of the 1960's therefore would seem to be evidence in favor of the proposition that controls retarded the growth of real wages. The fact that the decline in real wages was temporarily reversed in the months immediately following the termination of controls lends additional support to this proposition.

The *NEP* was an innovative policy undertaken by a capitalist government to achieve the complementary objectives of regaining America's international hegemony and restoring "balance" to the domestic economy. The mechanism was to be an economic expansion immunized against inflation and a profit squeeze through wage and price controls. It basically failed on both fronts. The *NEP* carried over unresolved into 1974 many of the domestic and international problems facing the *U.S.* economy in August 1971, and it severely exacerbated or created several others: inflationary pressures in general, and food price inflation in particular; debt and liquidity problems; shortages, speculative inventory buildups, and commodity inflation; secular profit and cashflow problems, temporarily alleviated by the controlled decline in real wages; the domestic inflationary impact of the declining value of the dollar; a fundamental, unresolved instability in the international sector. The basic problems of the economy in 1971 remained as 1974 began. The economy suffered from severe imbalances and disproportions requiring a massive recession it might not be able to withstand, and was situated in an international context of declining *U.S.* power amid system instability.

Some economists deny the assertion that the present international financial arrangements are unstable. They believe that floating exchange rates are the only mechanism consistent with international economic order. But we believe that the system of floating rates which emerged by default in the 1970's cannot serve as the basis for international economic stability. Floating rates are an interim arrangement that reflects the breakdown of international order attendant upon the relative decline in American power. It is understandable, therefore, that the Report's tone in its international section is one of relief that the system survived the year 1974.

The Report's discussion of floating rates is descriptive and uncritical. No attempt is made to celebrate the virtues of floating as opposed to fixed rates. No detailed discussion or analysis is made of the main issues traditionally associated with the flexible-fixed exchange rate discussion—independence of monetary-fiscal policy, exchange rate stability, depreciation and inflation, and trade deficit elimination through depreciation. The absence of discussion of these issues leaves the reader with the impression that the Report's authors understand that until a political resolution is reached, the world capitalist system will at best limp along with its managed float. But the Report underestimates the risks inherent in the present system. Widespread depression, oil import deficits, and the absence of political agreement are good reasons to fear protectionist policies and a major collapse in world trade.[19]

---

[18] See the special issue on corporate and consumer debt of *Business Week*, Oct. 12, 1974.

The proponents of floating rates, who have offered what are now seen by many as false promises, have met with widespread criticism.[20] Floating rates neither automatically equilibrate trade balances nor create independence of action for the monetary-fiscal authorities. Unless macropolicies are coordinated across national boundaries, policy actions trigger interest rate differentials which—in the context of enormous amounts of interest sensitive short-term capital, thin foreign exchange markets, and weak or uncertain expectations concerning future rates—exert effective and continuous pressure on exchange rates. Since policy makers are intensely concerned about the international position of their currency, the degree of policy independence created by managed floating is quite small.[21] Exchange rates, moreover, have been quite volatile since March of 1973. During 1974, for example, the dollar first fell 17.5 percent against the Deutschemark, then rose by 9.5 percent only to fall again to an end of the year low. Finally, in the absence of downward domestic price flexibility, dollar devaluation is a source of domestic inflationary pressure and exchange rate fluctuations are a source of world inflationary pressures.

In the long period of Pax Britannica and in the short period of Pax Americana, a fixed exchange rate system was the choice of the dominant economic power. Like any monopolist, the dominant power preferred to set prices rather than subject itself to the vagaries of the market. The existence of the current floating rate system is, in other words, proof that no international power is presently capable of reconstituting a new stable fixed-rate regime. While currently unavoidable, the present system is itself a contributor to international uncertainty and instability.

By late 1973 the macropolicy authorities were faced not only with all of the domestic and international problems and contradictions left unresolved by the *NEP*, but were confronted with an oil crisis as well. The Report devotes considerable attention to the oil problem, but fails to discuss the critical role played by the decline in *U.S.* world power in the development of this crisis. So long as this country enjoyed a virtual monopoly on world economic, political, and military power, it could depend on a guaranteed supply of cheap imported energy and raw materials. A weakened international position, however, made the United States unable to prevent the oil-producing countries from quadrupling the price of oil. That could not have happened in the 1950's—witness the *U.S.* orchestrated overthrow of the Iranian Prime Minister, Mossadegh, in 1953—and can therefore be taken as an extreme example of the process by which international instability destroys the basis for domestic stability.

IV. The Recession of 1974–75

Except for the introduction of extensive economic planning, the administration had no option other than to permit the economy to recess in late 1973. The stakes were high. The accumulated pressures described in the preceeding sections were more severe in 1973 than in late 1969. The controls were under extreme market pressure; the financial structure of businesses was imbalanced because of extensive debt financing; the rate of inflation was accelerating; and the international economy was in disarray. Nothing short of a major recession-depression could eliminate these imbalances from the system. While the impact of recessionary policies was uncertain, these policies were viewed as less risky than any of the perceived alternatives. The economy had to be purged. First fiscal and then monetary policy accomodated to this need.[22] Fiscal policy was restrictive beginning in the middle of 1973 and remained so throughout 1974. Monetary policy tightened in the second half of 1973 and became severely restrictive in the second half of 1974. The macropolicy authorities were attempting to generate a severe economic contraction. Skyrocketing unemployment rates in late 1974 left no doubt of their success. This policy jeopardizes a Republican victory in the 1976 elections just as the Democrats' Vietnam policy undermined their 1968 election prospects. But in both cases the policies were essential in order for the administrations to fulfill their responsibility to defend capitalist institutions. Unemployment and stagnation were the chosen first lines of defense.

---

[19] The possibility that a world depression might result from the relative decline in *U.S.* world hegemony is stressed by Kindleberger in his book on the Great Depression. He expresses the hope that either "cession of economic sovereignty to international institutions" or revival of American leadership will avoid such a crisis. For a more pessimistic outlook for world capitalism in the face of interimperialist rivalry between the EEC countries and the United States, see the Marxist analysis of Ernest Mandel.

[20] For a balanced review of the experience under floating rates, see Marina Whitman and comments by Paul Volcker. For a stronger dose of criticism of floating rates, see the comments of Kindleburger, Arthur Laffer, Paul Samuelson, and Volcker in *Business Week*, June 2, 1975.

[21] That the effect of monetary policy on the international value of the dollar constrains the domestic monetary authorities is certainly made clear in the public statements of Chairman Burns. For example, Edwin Dale in a recent New York Times column comments: "Arthur F. Burns . . . is letting it be known that a major constraint on how much the Federal Reserve can do is the international exchange rate of the dollar."

V. Prospects for the Future

Except for some tentative projections on unemployment and inflation rates in 1975, the Report itself does not speculate on the prospects for the remainder of this decade. The Office of Management and Budget has, however, provided the administration's projections for this period, and they present a dismal picture for working people. Starting from the optimistic assumption that the economy will witness an uninterrupted growth in real *GNP* averaging about 6 percent a year from 1976 through 1980, they project an average reported unemployment rate for the period of almost 7 percent, making the 1970's a decade of joblessness. To perceive the human impact of these forecasts, consider that the fraction of the work force who experience unemployment at some time during the year may be three or more times the average unemployment rate.

These projections, however, are not accompanied by any serious political-economic analysis of the forces likely to be operating on the *U.S.* economy over the remainder of the decade. Yet powerful secular pressures will clearly influence policy and performance. There will be a drive to reassert American control over a restabilized international economy, to reverse the decade-long decline in *U.S.* productivity, to close the gap between the percent of output channelled into capital accumulation here relative to Europe and Japan, to obtain what the Report calls "energy security," and to increase the rate of profit and decrease the growth of corporate debt. These objectives will not only influence policy but may lead to class struggle at home and rivalry and conflict abroad. They may also, in concert with the generally abysmal performance of the system over the past decade, induce major institutional change.

Given the conjunction of these pressures with the current economic stagnation, every option confronting those who control economic policy involves economic contradictions and policy conflict. American capital must engineer a long, noninflationary, balanced economic expansion within which the rate of capital accumulation dominates consumption growth. There appears to exist no single policy, and certainly no monetary-fiscal mix, that can achieve these objectives.

---

[22] In 1972, the high-employment budget was $7.6 billion in deficit. By the third quarter of 1973, this budget was in surplus and remained so throughout 1974. At an annual rate, the budget surplus was $8.1 billion in the fourth quarter of 1973 and $11.5 billion over the year 1974. The annual growth of the nominal money stock (M_1) was 8.6 percent from the beginning of 1972 through mid-1973. It declined to 5.5 percent over the next year. Then it fell precipitiously to 1.4 percent in the last half of 1974. Because of accelerating inflation in 1973–74, these figures severely understate the restrictiveness of monetary policy.

One option would be to initiate a strongly expansionary macropolicy which would generate full employment rather quickly. But this would lead to rapidly accelerating inflation, something neither the domestic nor the international economy can tolerate. A rapid *U.S.* expansion would lead to an international economic revival retriggering commodity inflation and a large increase in the world demand for oil—an ominous prospect indeed. Too many structural imbalances remain in the domestic economy to make possible a repeat of 1961 to 1965.

Another option would be to generate a long, gradual expansion much like the one projected in the budget in the hope that the years of high unemployment would hold wages down while production slowly edged upward. Meanwhile, the drive for a discrete jump in the rate of capital accumulation would be aided by fundamental changes in the tax system. Capital's demand for corporate tax relief has been widely supported. Every week brings new proposals by economists, politicians, or influential individual or organizational business spokesmen to lower the effective rate of corporate taxation and/or the income tax rate of the wealthy. A further move in the direction of a higher investment-consumption ratio may also be discerned in the current fiscal crises of state and local governments. In the context of budget crises, state and local governments are in the process of purging their welfare and employment rolls. The federal government apparently does not desire to relieve these fiscal pressures. This process, should it continue, will transfer resources from the public to the private sector and, by adding to the reserve army of the unemployed, will increase the downward pressure on wage rates.

The gradual expansion option has contradictions. Not only would it fail to guarantee price stability, but its long years of intolerable unemployment rates raise the prospect of heightened class conflict in the United States. Although the leaders of organized labor have been incredibly docile up to this point, they may not be able to restrain rank and file anger for the duration of the decade. A slow recovery would create even more acute labor problems in Europe and perhaps even Japan. Finally, the desired acceleration of capital accumulation might not be sustainable if working class incomes and consumption demand are restricted. Even a gradual expansion may abort under these circumstances.

Alternatively, the government might initiate an incomes policy of wage-price and perhaps profit and interest rate controls administered in a manner similar to those of the *NEP*. These controls might be used to augment one of the monetary-fiscal strategies discussed above. A target rate of inflation, coupled with a rule that money wage rate changes must on average equal this target rate of inflation plus the rate of growth of productivity, might set the stage for expansive macropolicy by freezing labor's share. But if we add an unusually high target rate of capital accumulation, a reduction of labor's share would be necessary.

Such an augmented incomes policy poses difficult questions. Can demand be sustained in the face of a declining share of income for labor? Will labor tolerate a lower share of output? An incomes policy, moreover, is essentially self-contradictory in the context of a capitalist economy. We accept as generalizable the Report's assertion that the *NEP* at some point in the expansion "began to obstruct normal supplier-purchaser relationships, and in some cases the controls became quite unworkable" (pp. 228–29). Unless more extensive micro or sectoral planning is introduced, a permanent system of wage-price controls is untenable.

Economic planning may be the wave of the future, even under capitalism; it represents an option, perhaps *the* option in the long run. Several notable planning proposals have already been made but they do not envision a fully planned economy as we normally understand this concept. They deal more with gathering information, making forecasts, using some tax and subsidy incentives and marginally altering resource allocation. But it is clear to us that if planning is to help resolve major contradictions in the domestic economy, it must achieve a significant substitution of administrative for market processes. Genuine planning could involve not only the setting of wages and prices, but government-directed allocation of raw materials and credit, a detailed system of tax subsidies and penalties, antistrike or even anticollective bargaining legislation, and administratively coordinated investment strategies among firms and industries.

Although pressure toward planning is likely to continue, it will not be steady. While a brief period of relatively trouble-free expansion may temporarily silence supporters of planning, renewed outbreaks of inflation, rising unemployment, credit crises, and/or shortages will intensify this pressure. Planning may represent the only way to eliminate recurrent crises from the domestic economic system and to successfully pursue the goal of *U.S.* domination of the world capitalist system. Only within a planned economy is it potentially possible to achieve full employment and price stability and at the same time restrain wages and consumption in support of capital accumulation. But planning demystifies economic power relations and transfers the stresses and strife of the market system into the political arena. It therefore portends political conflict of the highest order—conflict within the capitalist class as well as between capital and labor.

Within the present array of political forces in the United States, the development of economic planning will undoubtedly mean corporate control of the planning process, just as the introduction of federal regulatory agencies has historically meant control by and for the regulated industries. It is, therefore, more important than ever before that the political balance of power be changed and the power of the corporate elite broken. Working people and their allies must defend the interests of the majority of the American people against the fundamentally antagonistic interests of the corporations and the super-rich who own and control them.

Securities Market Efficiency in an Arrow-Debreu Economy

By MARK RUBINSTEIN*

The word "efficiency" as applied to securities markets has unfortunately been used to represent a variety of logically distinct concepts. In particular, it may mean:

> a) Exchange efficiency: participants are not motivated to create exchange arrangements not already provided by the market.
>
> b) Production efficiency: value-maximizing firms make Pareto optimal production decisions.
>
> c) Information efficiency: present security prices are costlessly known to all participants and information about future security prices is "fully reflected" in these present prices.

To focus undiluted attention on information efficiency, the concepts a) and b) will be automatically satisfied by the Arrow-Debreu model used in this paper.[1] Moreover, since transactions costs are assumed nonexistent (i.e., perfect market), the remaining question and chief focus of this paper is: when will present security prices fully reflect information about future prices?

This question should first serve to raise the logically prior question, what do we mean by the phrase "fully reflect information"? In a perfect and competitive economy composed of rational individuals with homogeneous beliefs about future prices, by any meaningful definition present security prices must fully reflect all available information about future prices. According to Eugene Fama,

> First, it is easy to determine *sufficient* conditions for capital market efficiency. For example, consider a market in which (i) there are no transactions costs in trading securities, (ii) all available information is costlessly available to all market participants, and (iii) all agree on the implications of current information for the current price and distributions of future prices of each security. In such a market, the current price of a security obviously "fully reflects" all available information. [p. 387]

Moreover, the model of the securities market developed here will be informationally efficient in this trivial case. The conditions for efficiency only become interesting when participants have heterogeneous beliefs (or face positive transactions costs, not considered here). In this case, it seems obvious that some may perceive their information as fully reflected in present prices, while others may not. The challenge is to identify who is who, or to put it somewhat more abstractly, to identify what information is and is not reflected in present prices. A precise analytical definition of information-efficiency is developed below. I shall argue that despite some attempts (see Fama and Paul Samuelson), its definition under nontrivial circumstances has remained ambiguous.

---

* Assistant professor, Graduate School of Business Administration, University of California, Berkeley. Research for this paper was supported in part by a grant from the Dean Witter Foundation. I am indebted to Jack Hirshleifer for many discussions as well as previous collaboration. However, I alone bear any responsibility for errors in this paper.

[1] In the context of an incomplete market for securities, exchange and production efficiency both hold whenever there is universal portfolio separation so that at each date all individuals divide their wealth among consumption and the same two mutual funds, one of which is risk free. (See the author, 1973, 1974.)

Section I details a model constructed to answer these questions. Section II develops a precise definition of information efficiency and identifies the characteristics of participants who believe present security prices fully reflect their information. Section III examines implications for the intertemporal structure of security rates of return (random walk, unbiased term structure). Section IV contrasts the definition of information efficiency with those of Fama and Samuelson. Section V mentions the chief limitations of the model in view of the issues addressed.

I. The Economy

Appropriate answers to the questions posed require a model of a dynamic, uncertain, heterogeneous[2] economy. Assume each individual in the economy makes decisions over a three-date (t=0, 1, 2) horizon. At date t=0, he chooses present consumption C_0 and makes a *provisional* choice of future consumption by selecting a portfolio of contingent claims $\{\hat{C}_e\}$ to date t=1 consumption which pay off only if state *e* occurs at date t=1, and by selecting a portfolio of contingent claims $\{\hat{C}_s\}$ to date t=2 consumption which pay off only if state *s* occurs at date t=2. Consequently, if $\{P_e\}$ and $\{P_s\}$ denote, respectively, the date t=0 prices to these claims,[3] the individual will divide his date t=0 wealth W_0 so that $C_0+\Sigma_e P_e\hat{C}_e+\Sigma_s P_s\hat{C}_s=W_0$.

At date t=1, the true state *e* occurs: contingent claims to that state pay off, contingent claims to other states at that date become worthless, and new information becomes available and is dispersed perhaps unevenly throughout the economy. This information revises beliefs held by individuals concerning prices to rule in the market at date t=2. As a consequence, and also due to the mere passage of time, the equilibrium prices of contingent claims to date t=2 consumption are revised from their prior levels set at date t=0. Since these revised prices will in general depend on state *e*, they are denoted $\{P_{s\cdot e}\}$. The individual's wealth W_e at date t=1 will therefore depend both on state *e* and on his prior choices so that $W_e\equiv\hat{C}_e+\Sigma_s P_{s\cdot e}\hat{C}_s$. In view of the revised prices, each individual with his own revised beliefs will in general desire to revise his provisional choices $\hat{C}_e$ and $\{\hat{C}_s\}$ made at date t=0. To accommodate this, denote C_e and $\{C_{s\cdot e}\}$ as his revised (and final) choice of date t=1 consumption and portfolio of contingent claims to date t=2 consumption (in general, $C_e \neq \hat{C}_e$ and $\{C_{s\cdot e} \neq \hat{C}_s\}$). The subscript e reflects that his revision at date t=1 will in general depend on the true state at that date and consequently, after revision, to satisfy his wealth constraint $C_e + \Sigma_s P_{s\cdot e} C_{s\cdot e} = W_e$. Date t=1 is the last time choices are made. At date t=2 the true state s occurs: contingent claims to that state pay off, and contingent claims to other states become worthless. Consequently, the individual simply consumes $C_{s\cdot e}$.

---

[2] Specifically, resources, beliefs, and tastes are generally different for different individuals while they all share the same opportunities (i.e., face the same prices of securities—an implication of competitive markets).

[3] A type of complete market has been assumed. For complete markets in the Debreu sense (pp. 98–102), a complete set of consumption claims to date t=2 consumption would need to be available at date t=0 with payoffs if and only if *both state s and state e* occur. With these claims available, the exchange opportunities at date t=0 would be sufficiently rich that no individual would need to revise his portfolio at date t=1 and a market at that date would be redundant. It is well known that if such claims exist, then the equilibrium will be Pareto optimal; in particular, no individual will have an incentive to create additional securities or engage in transactions outside the market. However, these claims do *not* exist in the economy described in this paper; nonetheless, the equilibrium will still be Pareto optimal since it can be shown to yield exactly the same allocations as if these claims did exist. The general principle is that individuals are indifferent between relatively rich forward markets with few future revision opportunities and relatively poorly developed forward markets with many future trading dates. In reality, market setup costs and economies of scale in exchange will help determine this tradeoff. The objections raised against the assumption of rich forward markets lose a great deal of force if one recognizes that individuals may be able to make the same final choices even in the absence of some forward markets, provided sufficient opportunities for revision exist. One need only recall the virtually continuous trading provided by stock exchanges to lend strength to this position. See Kenneth Arrow and commentary by Jacques Dreze, pp. 144–45, for the genesis of this argument. In particular, it presumes future security prices are correctly forecast; see Section V of this paper for further discussion.

All individuals are presumed to obey the Savage axioms of rational choice: they have heterogeneous beliefs and tastes, representable by probabilities and utility functions, so that they make choices which maximize expected utility. The term $\pi_e > 0$ denotes the probability held by an individual that state e will occur; given the occurrence of state e, $\pi_{s\cdot e} > 0$ denotes the conditional probability that state s will occur; by the laws of probability, the unconditional probability that state s will occur $\pi_s = \Sigma_e \pi_e \pi_{s\cdot e}$. Just as prices of contingent claims to date t=2 consumption may be revised at date t=1, beliefs may be similarly revised (in general, $\{\pi_{s\cdot e} \neq \pi_s\}$). Each individual is assumed to maximize an additive, state-independent utility function over his final consumption plan (C_0, $\{C_e\}$, $\{C_s\}$). That is, the utility of consumption $U_t(\cdot)$ at date t is evaluated independently of consumption at all other dates (but may depend on the date itself) and independent of states.[4]

The following programming problem summarizes the above description:[5]

$$\max_{C_0, \{\hat{C}_e\}, \{\hat{C}_s\}, \{C_e\}, \{C_{s\cdot e}\}} \quad U_0(C_0) + \Sigma_e \pi_e U_1(C_e)$$
$$+ \Sigma_e \pi_e \Sigma_s \pi_{s\cdot e} U_2(C_{s\cdot e})$$

subject to $W_0 = C_0 + \Sigma_e P_e \hat{C}_e + \Sigma_s P_s \hat{C}_s$

$$C_e + \Sigma_s P_{s\cdot e} C_{s\cdot e} = W_e \equiv \hat{C}_e + \Sigma_s P_{s\cdot e} \hat{C}_s \qquad \text{(all } e\text{)}$$

Factoring and using Lagrangian multipliers,[6] the problem may be restated

$$\max_{C_0, \{\hat{C}_e\}, \{\hat{C}_s\}, \{C_e\}, \{C_{s\cdot e}\}} \quad U_0(C_0)$$
$$+ \Sigma_e \pi_e U_1(C_e) + \Sigma_s \pi_{s\cdot e} U_2(C_{s\cdot e})$$
$$- \lambda_e[C_e + \Sigma_s P_{s\cdot e} C_{s\cdot e} - \hat{C}_e - \Sigma_s P_{s\cdot e} \hat{C}_s]$$
$$- \lambda_0[C_0 + \Sigma_e P_e \hat{C}_e + \Sigma_s P_s \hat{C}_s - W_0]$$

The necessary and sufficient conditions for an optimum are determined by differentiating the maximand partially with respect to each choice variable and repeating the constraints. Differentiating successively by C_0, $\{\hat{C}_e\}$, $\{\hat{C}_s\}$, $\{C_e\}$, and $\{C_{s\cdot e}\}$,

$$U'_0(C^*_0) = \lambda_0$$

---

[4] For a more general portfolio model, excepting its assumption of constant proportional risk aversion, see Nils Hakansson, who allows for incomplete markets, uncertain lifetime, and state-dependent utility. The salient feature of his model, as well as the one presented in this paper, is the freedom of prices to follow the most generalized (discrete-time) stochastic process.

[5] Assume that $U'_t > 0$ and $U''_t < 0$. Nonnegativity constraints on actual consumption (C_0, $\{C_e\}$, $\{C_{s\cdot e}\}$) are to be satisfied although they are not explicitly incorporated into the analysis. For at least one class of utility functions, U_t, those with constant proportional risk aversion, the nonnegativity constraints are automatically satisfied since for this class the marginal utility of consumption is infinite at zero consumption.

[6] Use here has been made of stochastic Lagrangian multipliers, which are a natural generalization of standard Lagrangian techniques. (For example, see Dreze.) Formulating the programming problem in this way permits it to be solved without explicitly working backwards via a derived utility function as in dynamic programming. Had we done so, for the date t=1 subproblem contained in the large brackets, the derived utility of wealth function

$$V_e(W_e) \equiv \max_{C_e, \{C_{s\cdot e}\}} U_1(C_e) + \Sigma_s \pi_{s\cdot e} U_2(C_{s\cdot e})$$
$$- \lambda_e[C_e + \Sigma_s P_{s\cdot e} C_{s\cdot e} - W_e]$$

where $W_e = \hat{C}_e + \Sigma_s P_{s\cdot e} \hat{C}_s$. In general, even though utility over consumption is state-independent, the derived utility function $V_e(W_e)$ of date t=1 wealth will not be state independent. It will depend on state e not merely indirectly through W_e but also through the revised state-dependent prices and beliefs. With this subproblem solved, the date t=0 problem reduces to

$$\max_{C_0, \{\hat{C}_e\}, \{\hat{C}_s\}} U_0(C_0) + \Sigma_e \pi_e V_e(W_e)$$
$$- \lambda_0[C_0 + \Sigma_e P_e \hat{C}_e + \Sigma_s P_s \hat{C}_s - W_0$$

$$\pi_e\lambda_e = \lambda_0 P_e \qquad \text{(all } e\text{)}$$

$$\Sigma_e \pi_e \lambda_e P_{s\cdot e} = \lambda_0 P_s \qquad \text{(all } s\text{)}$$

$$U_1'(C_e^*) = \lambda_e \qquad \text{(all } e\text{)}$$

$$\pi_{s\cdot e} U_2'(C_{s\cdot e}^*) = \lambda_e P_{s\cdot e} \qquad \text{(all } s \text{ and } e\text{)}$$

The stochastic Lagrangian multipliers $\{\lambda_e\}$ play the role of linking the decision problems at dates t=0 and t=1. Eliminating the Lagrangian multipliers and rearranging, the necessary and sufficient conditions for an optimum can be symmetrically represented by

$$(1) \qquad P_s = \Sigma_e P_e P_{s\cdot e} \qquad \text{(all } s\text{)}$$

$$(2) \qquad \pi_e U_1'(C_e^*) = U_0'(C_0^*) P_e \qquad \text{(all } e\text{)}$$

$$(3) \qquad \pi_{s\cdot e} U_2'(C_{s\cdot e}^*) = U_1'(C_e^*) P_{s\cdot e} \qquad \text{(all } e \text{ and } s\text{)}$$

$$(4) \qquad W_0 = \Sigma_s P_s \hat{C}_s^* + \Sigma_e P_e \hat{C}_e^* + C_0^*$$

$$(5) \qquad \Sigma_s P_{s\cdot e} C_{s\cdot e}^* + C_e^* = \Sigma_s P_{s\cdot e} \hat{C}_s^* + \hat{C}_e^* \quad \text{(all } e\text{)}$$

Condition (1) is an arbitrage relationship among prices, paralleling $\pi_s = \Sigma_e \pi_e \pi_{s\cdot e}$, which must hold in equilibrium. Conditions (2) and (3) are the standard single-period optimality conditions linking marginal utility to prices, and conditions (4) and (5) repeat the constraints.

Let i superscript individuals and ($\overline{C}_0^i$, $\{\overline{C}_e^i\}$, $\{\overline{C}_s^i\}$) represent the endowment of individual i so that $W_0^i \equiv \overline{C}_0^i + \Sigma_e P_e \overline{C}_e^i + \Sigma_s P_s \overline{C}_s^i$. The closure conditions then needed to endogenously determine equilibrium prices would be

$$\Sigma_i C_0^i = \Sigma_i \overline{C}_0^i$$

$$\Sigma_i C_e^i = \Sigma_i \hat{C}_e^i = \Sigma_i \overline{C}_e^i \qquad \text{(all } e\text{)}$$

$$\Sigma_i C_{s\cdot e}^i = \Sigma_i \hat{C}_s^i = \Sigma_i \overline{C}_s^i \qquad \text{(all } e \text{ and } s\text{)}$$

The i superscript will continue to be omitted, unless there is danger of ambiguity.

II. Nonspeculation and Consensus

We will now use conditions (1)–(5) to determine what information about future prices is fully reflected in present prices. We shall first provide a precise definition of prices that fully reflect the *new information* that becomes available to an individual at date t=1; then this will be extended to a definition of prices that fully reflect *all information* available to an individual at both dates t=0 and t=1.

An individual will be said to perceive the new information that becomes available to him as fully reflected in revised security prices if and only if he has "nonspeculative beliefs." By definition, *nonspeculative beliefs are those beliefs for which no portfolio revision is an optimal strategy.*[7] The model described in Section I has been constructed to motivate this definition.

Observe that the variety of consumption claims available at date t=0 is just sufficient for an individual to move directly to his optimal final consumption plan by choosing $\{C_e^* = \hat{C}_e^*\}$ and $\{C_{s\cdot e}^* = \hat{C}_s^*\}$. In this case, he opts not to revise his portfolio at date t=1, but stays with his date t=0 provisional choices. This might well be optimal since one of the chief reasons for portfolio revision—availability of new consumption claims at future dates—is absent. At date t=0, an individual can purchase claims to consumption at every state that might occur at dates t=1 and t=2. Other possible causes of portfolio revision—barriers to marketability occasioned by nonmarketable resources, short selling restrictions, and finite transactions costs, as well as state-dependent tastes—are omitted from the model.

---

[7] Joseph Stiglitz also identifies speculation with portfolio revision. Using a three-date model, he examines the relationship between the term structure and an individual's demand for short- vs. long-term bonds. At date t=0, individuals choose between short- and long-term bonds. At date t=1, the previous short-term bonds mature and the previous long-term bonds now become the only existing short-term bonds. Individuals can revise their portfolios, choosing between consumption and the short-term bonds. At date t=2, they consume their remaining wealth. Stiglitz introduces uncertainty by assuming the date t=1 price of the long-term bonds is uncertain at date t=0. Unfortunately, since Stiglitz admits no purely risky securities into his model, in an equilibrium context his economy is riskless and the injected uncertainty disappears together with the purpose of his model.

In fact, the economy has been so constructed as to leave only one reason for portfolio revision: a change in prices to claims to date t=2 consumption that is not fully offset by revised beliefs. In general, for claims under some state s, price changes from P_s at date t=0 to $P_{s\cdot e}$ at date t=1 if state e occurs. Similarly, on the basis of newly received information about the future state s, an individual revises his belief from π_s at date t=0 to $\pi_{s\cdot e}$ at date t=1 if state e occurs. Since his portfolio chosen at date t=0 was based on price P_s and belief π_s, with revised price and belief at date t=1, the individual will generally desire to revise his portfolio. For example, even without formal analysis, it should be intuitively obvious that if $P_{s\cdot e}<P_s$ and $\pi_{s\cdot e}>\pi_s$, then the individual will typically shift more of his holdings into consumption claims to state s (i.e., $C^*_{s\cdot e}>\hat{C}^*_s$).

However, if the change in price from P_s to $P_{s\cdot e}$ were in some sense precisely offset by the change in belief from π_s to $\pi_{s\cdot e}$ and this occurred for all states s and e, then the individual would plan not to revise his portfolio at date t=1 regardless of the state e that occurs at that date. If this offsetting effect occurs, then we shall say the individual has nonspeculative beliefs and revised prices fully reflect the new information received by the individual at date t=1. Consequently, to identify nonspeculative beliefs and prices that fully reflect new information, we need only examine the circumstances under which no portfolio revision is optimal.

THEOREM (Nonspeculation Condition): *No portfolio revision under all states e is optimal* ($\{C^*_e=\hat{C}^*_e\}$ *and* $\{C^*_{s\cdot e}=\hat{C}^*_s\}$) *if and only if*

$$\frac{\pi_s}{P_s}=\frac{\pi_e\pi_{s\cdot e}}{P_eP_{s\cdot e}}\qquad (\textit{all } s \textit{ and } e)$$

PROOF:

Applying conditions (1)–(5), we will (i) develop necessary and sufficient conditions for $C^*_{s\cdot e}$ to be independent of e; and (ii) show that in this case, given $C^*_{s\cdot e}$ and C^*_e, it is feasible to move immediately to these choices at date t=0.

(i) Substituting condition (2) into (3):

$$\frac{U_0'(C_0^*)}{U_2'(C^*_{s\cdot e})}=\frac{\pi_e\pi_{s\cdot e}}{P_eP_{s\cdot e}}$$

If $C^*_{s\cdot e}$ is independent of e, then there exists a number k_s independent of e so that $k_s\equiv(\pi_e\pi_{s\cdot e})/(P_eP_{s\cdot e})$. Summing over states e, $k_s(\Sigma_eP_eP_{s\cdot e})=\Sigma_e\pi_e\pi_{s\cdot e}$, which by condition (1) and the laws of probability implies $k_sP_s=\pi_s$. Consequently, $\pi_s/P_s=(\pi_e\pi_{s\cdot e})/(P_eP_{s\cdot e})$. Moreover, if this last equation holds, then $U_0'(C_0^*)/U_2'(C^*_{s\cdot e})=\pi_s/P_s$ so that $C^*_{s\cdot e}$ must be independent of e. In summary, we can define C^*_s so that $C^*_{s\cdot e}\equiv C^*_s$ if and only if $\pi_s/P_s=(\pi_e\pi_{s\cdot e})/(P_eP_{s\cdot e})$. This holds for all s and e.

(ii) It remains to show $\{C^*_s=\hat{C}^*_s\}$ and $\{C^*_e=\hat{C}^*_e\}$. To accomplish this we need only verify that these choices are feasible at date t=0, since in this case the individual would be willing to move immediately to $\{C^*_s\}$ and $\{C^*_e\}$ at date t=0 and not revise his portfolio at date t=1. Multiplying condition (5) by P_e

$$\Sigma_sP_eP_{s\cdot e}C^*_s+P_eC^*_e=\Sigma_sP_eP_{s\cdot e}\hat{C}^*_s+P_e\hat{C}^*_e$$

and summing over e

$$\Sigma_s(\Sigma_eP_eP_{s\cdot e})C^*_s+\Sigma_eP_eC^*_e=\Sigma_s(\Sigma_eP_eP_{s\cdot e})\hat{C}^*_s+\Sigma_eP_e\hat{C}^*_e$$

By conditions (1) and (4)

$$\Sigma_sP_sC^*_s+\Sigma_eP_eC^*_e=\Sigma_sP_s\hat{C}^*_s+\Sigma_eP_e\hat{C}^*_e=W_0-C_0^*$$

so that

$$\Sigma_s P_s C_s^* + \Sigma_e P_e C_e^* + C_0^* = W_0$$

Consequently, $\{C_s^*\}$ and $\{C_e^*\}$ could have been chosen immediately at date $t=0$.

A similar result has been derived by Jack Hirshleifer and the author in a somewhat less general context. In that paper, it was emphasized that, surprisingly, the nonspeculation condition depends only on the relationship between beliefs and prices, not on resources and tastes.[8] Apparently the variety of consumption claims available in the market at date $t=0$ is sufficiently rich that desired exchange generated solely by differences among individuals in resources and tastes is satisfied by exchange permitted at date $t=0$. In this paper, another implication will be emphasized. Rewriting the nonspeculation condition,

$$\frac{P_{s\cdot e}/P_s}{\pi_{s\cdot e}/\pi_s} = \frac{\pi_e}{P_e}$$

The right-hand side is a number fully determined before state e becomes known; it is a constant of proportionality between revised prices and beliefs, predetermined at date $t=0$, which must hold for no revision to be optimal. Imagine the following vignette:

At date $t=0$, prices $P_e=1/2$ and $P_s=1/20$ are set in the market. From the point of view of one individual $\pi_e=1/2$ and $\pi_s=1/10$. Consequently, $\pi_e/P_e=1$. On the basis of new information received at date $t=1$ under the occurrence of state e, the individual doubles the probability he now attaches to state s ($\pi_{s\cdot e}=1/5$). Before consulting the market, the individual decides to purchase more contingent claims to consumption under state s if its price has not risen sufficiently. However, new information (but not necessarily the same information) may also have become available to other participants in the market, causing them also to revise their beliefs. As a result, a new equilibrium price will be set on the contingent claims. In fact, if the price exactly doubles ($P_{s\cdot e}=1/10$), then the individual will stand pat and not alter his holdings. Why? Because from his point of view, the new information he has received is already fully reflected in the revised price $P_{s\cdot e}$.

If all individuals have homogeneous beliefs, do they all regard the new information they receive at date $t=1$ as fully reflected in revised prices? If the above definition of fully reflected is meaningful, the answer should be positive. Fortunately,

COROLLARY: *If all individuals have homogeneous beliefs, then all individuals have nonspeculative beliefs.*

PROOF:

It follows trivially from the previous theorem that $C_{s\cdot e}^* > (<) \hat{C}_s^*$ if and only if $\pi_s/P_s < (>) \pi_e \pi_{s\cdot e}/P_e P_{s\cdot e}$ (all s and e). If one individual revises his portfolio so that $C_{s\cdot e}^* > \hat{C}_s^*$, by closure, since $\Sigma_i C_{s\cdot e}^i = \Sigma_i \hat{C}_s^i$, there must be some other individual for whom $C_{s\cdot e}^* < \hat{C}_s^*$; but in this case, by the above, the beliefs of both cannot be the same. Hence, the theorem is proved by contradiction.

Although homogeneous beliefs are sufficient for all individuals to see their new information fully reflected in the revised prices, they are not necessary. From the nonspeculation condition, a necessary as well as sufficient condition is that all individuals must have nonspeculative beliefs, that is, agree on the *ratio* $\pi_e \pi_{s\cdot e}/\pi_s$, but with possible disagreement over its components.

For *all* information, not merely new information, to be fully reflected in prices, a stronger condition than nonspeculative beliefs is required. We will say an individual perceives all the information he has and will receive as fully reflected in security prices if and only if he has "consensus beliefs." By definition, *consensus beliefs are those beliefs which, if held by all individuals in an otherwise similar economy, would generate the same equilibrium prices as in the actual heterogeneous economy.* In other words, consensus beliefs are the homogeneous beliefs that would sustain the same equilibrium prices. To motivate this definition, imagine the following vignette:

---

[8] However, while the decision to revise does not depend on resources and tastes, the *extent* of revision does.

> Jack, curious to learn if all his information is fully reflected in prices, visits the Great Economist in the Sky. Knowing the resources and tastes of every participant in the economy, as well as the actual equilibrium prices, the Great Economist calculates whether or not those same prices would rule if every individual had the same beliefs as Jack. Discovering that different equilibrium prices would emerge, the Great Economist concludes that either Jack has valuable information (i.e., it would alter prices if publicly announced) not fully reflected in prices or that other individuals have information affecting prices not known to Jack.

Unfortunately, unlike nonspeculative beliefs, consensus beliefs admit of no simple and general mathematical formulation; they will depend directly on the resources, tastes, and beliefs of all individuals in the economy.[9]

If this interpretation of consensus beliefs is to be meaningful, then surely an individual with consensus beliefs must see his *new* information at date t=1 as fully reflected in revised prices. This is indeed the case since

COROLLARY: *If an individual has consensus beliefs, then he has nonspeculative beliefs.*

PROOF:

By definition of consensus beliefs, an individual who has them can be viewed as a member of an otherwise similar economy, except in which these beliefs are held by everyone. Moreover, by the previous corollary, everyone in a homogeneous economy has nonspeculative beliefs. But since both economies have the same equilibrium prices, nonspeculative beliefs are the same in both economies. Therefore, the individual with consensus beliefs must also

---

[9] This raises the prior question of conditions for the existence of consensus beliefs. In the usual existence problem we input heterogeneous probabilities and solve for nonnegative homogeneous prices. In this case, we input homogeneous prices (which hold in the heterogeneous economy) and solve for homogeneous probabilities (i.e., nonnegative real numbers which sum to one). Unlike prices, these homogeneous probabilities may not exist. While the derivation of necessary and sufficient conditions for their existence is not contemplated here, some sufficient conditions are given as an illustration. In particular, suppose all individuals maximize weighted logarithmic utility functions with the same constant rate of patience; that is, $U_t^i(\cdot)=\rho^t ln(\cdot)$ where $\rho>0$. In this case, it is easily shown that at the optimum $C_0^i=W_0^i(1+\rho+\rho^2)^{-1}$. Substituting this into conditions (2)

$$\pi_e^i \rho C_0^i = C_e^i P_e$$
$$\rho(1+\rho+\rho^2)^{-1}\pi_e^i W_0^i = C_e^i P_e$$

and summing over i and by closure,

$$\rho(1+\rho+\rho^2)^{-1}\Sigma_i \pi_e^i W_0^i = P_e \Sigma_i C_e^i = P_e \Sigma_i \bar{C}_e^i$$

If π_e^M were the consensus belief for state e, then this condition in the homogeneous economy would simplify to

$$\rho(1+\rho+\rho^2)^{-1}\pi_e^M \Sigma_i W_0^i = P_e \Sigma_i \bar{C}_e^i$$

Comparing these two results, the consensus belief

$$\pi_e^M = \Sigma_i \frac{W_0^i}{\Sigma_i W_0^i}\pi_e^i \qquad \text{(all } e\text{)}$$

which is indeed a nonnegative real number such that $\sum_e \pi_e^M=1$. Since similar results hold for conditions (3), and (1), (4), and (5) are trivially satisfied, consensus beliefs exist. In the logarithmic case, they are simply weighted *arithmetic* averages of actual beliefs. See Robert Wilson for illustrations of consensus beliefs if all individuals have exponential utility, in which case they are weighted *geometric* averages of actual beliefs.

have nonspeculative beliefs in the actual heterogeneous economy. (It should be similarly clear that the converse of this corollary is false.)

In sum, we have a triplet of increasingly stronger conditions that capture what is meant by prices fully reflect information: 1) nonspeculative beliefs; 2) consensus beliefs; 3) homogeneous beliefs.

Condition 3) implies 2) and 2) implies 1), but the converses of these implications are false. Condition 3) is sufficient and if consensus beliefs are unique, necessary for *all* individuals to perceive *all* information fully reflected in prices. Condition 2) is necessary and sufficient for *an* individual to perceive *all* his information fully reflected in prices. Condition 1), if true for all individuals, is necessary and sufficient for *all* individuals to perceive *new* information fully reflected in prices; and 1) is necessary and sufficient for *an* individual to perceive his *new* information fully reflected in prices.

Of course, all effects of uncertainty (without assuming it away) on the allocation of resources can be completely exorcised from the economy if individuals have "clairvoyant homogeneous beliefs." By definition, *clairvoyant homogeneous beliefs are beliefs that generate the same allocation of resources as would have emerged in otherwise similar but certain economies, one for each possible sequence of states.* That is, the realized allocation in the uncertain economy is the same allocation that would have emerged in an otherwise similar economy, but where the true sequence of states was known by all individuals in advance of any trading. An economy composed of identical individuals is a trivial instance of clairvoyance, since irrespective of beliefs there is no trading.

III. Rates of Return

The past decade has witnessed the development and testing of theoretical models of the contemporaneous structure of security rates of return under uncertainty. These models, as typified by variants of the popular mean-variance model, describe the relationship among rates of return of *different securities* at the *same date.* Concurrently, there has been considerable empirical research on the intertemporal structure of rates of return of the *same security* at *different dates.* This research has been directed at verification of a variety of statistical hypotheses such as the existence of an unbiased term structure and characteristics of a random walk. However, excepting the incipient work of a very few authors—Jerry Green and John Long—no one has attempted to provide a theoretical basis for these hypotheses in an equilibrium context.

The nonspeculation condition implies restrictions on the intertemporal structure of security rates of return as viewed by individuals who perceive the securities market as informationally efficient. To see this, translating prices into rates of return, let

$$1 + r_{1s\cdot e} \equiv P_{s\cdot e}/P_s$$

$$1 + r_{2s\cdot e} \equiv P_{s\cdot e}^{-1}$$

$$1 + r_{1F} \equiv (\Sigma_e P_e)^{-1}$$

$$1 + r_{2Fe} \equiv (\Sigma_s P_{s\cdot e})^{-1}$$

$$(1 + R_{2F})^2 \equiv (\Sigma_s P_s)^{-1}$$

Using these definitions, we state the following theorem:

THEOREM (Nonspeculative Intertemporal Structure): *In terms of nonspeculative beliefs,*

$$E[(1 + r_{1s})(1 + r_{2s})] = (1 + r_{1F})E[1 + r_{2s}]$$

where the expectations are assessed with respect to beliefs held at date $t = 0$.

PROOF:

By the nonspeculation condition,

$$\frac{\pi_s}{P_s} P_e = \pi_e \frac{\pi_{s\cdot e}}{P_{s\cdot e}}$$

Summing over states e and rearranging

$$\pi_s P_s^{-1} = (\Sigma_e P_e)^{-1}(\Sigma_e \pi_e \pi_{s\cdot e} P_{s\cdot e}^{-1})$$

Since $\pi_s = \Sigma_e \pi_e \pi_{s\cdot e}$,

$$\Sigma_e \pi_e \pi_{s\cdot e}\left(\frac{P_{s\cdot e}}{P_s} P_{s\cdot e}^{-1}\right) = (\Sigma_e P_e)^{-1}(\Sigma_e \pi_e \pi_{s\cdot e} P_{s\cdot e}^{-1})$$

The conclusion follows immediately upon substituting rate of return notation.

In words, the intertemporal structure of rates of return implied by nonspeculative beliefs (and hence by consensus or homogeneous beliefs) must have the following characterization: *the expected one plus compound rate of return on any security discounted by one plus the first-period risk-free rate equals its expected one plus second-period rate of return, where the expectations are assessed with respect to beliefs at the beginning of the first period.*[10]

If we assume this minimal characterization of the intertemporal structure, can we confirm or reject any popular statistical hypotheses? Some trial hypotheses are listed below:

(A) **No Risk Adjustment**

$$1 + r_{1F} = E[1 + r_{1s}]$$

(B) **Uncorrelated Rates**

$$E[(1 + r_{1s})(1 + r_{2s})] = E[1 + r_{1s}]E[1 + r_{2s}]$$

(C) **Uncorrelated Inverse Rates**

$$E[(1 + r_{1s})^{-1}(1 + r_{2s})^{-1}] = E[(1 + r_{1s})^{-1}]E[(1 + r_{2s})^{-1}]$$

(D) **Unbiased Inverse Term Structure**

$$(1 + R_{2F})^{-2} = (1 + r_{1F})^{-1}E[(1 + r_{2F})^{-1}]$$

It follows immediately from the previous theorem that in terms of nonspeculative beliefs, (A) and (B) are equivalent. That is, *the expected first-period rate of return on any security equals the first-period risk-free rate if and only if its intertemporal sequence of one plus rates of return are serially uncorrelated.* Consequently, we cannot simultaneously believe in a risky economy composed of risk-averse individuals and observe *ex ante* serially uncorrelated (and, hence, observe serially independent) one plus rates of return. However, although hypotheses (A) and (B) may be rejected, neither hypothesis (C) nor (D) can be confirmed or rejected in the presence of nonspeculative beliefs. Serially uncorrelated rates of return, as, for example, surveyed in Fama, have played a significant role in the guise of the random walk hypothesis in statistical tests of information efficiency. However, the theoretical analysis provided here indicates that at least some forms of the random walk hypothesis are inconsistent with information efficiency. To obtain a more specific characterization of the intertemporal structure of security rates of return, it is necessary to impose stronger assumptions than mere nonspeculation.

IV. Concepts of Information Efficiency

It is instructive to contrast the concept of information efficiency developed in this paper with other discussions in the literature. To paraphrase Fama, efficiency is defined as follows:

> Using information set ϕ, forecast the probability distribution of the prices of securities that will be realized at date t=1. Input this data into a model of market equilibrium determining expected rates of return. From these and the expected date t=1 prices, the date t=0 prices, *given* information set ϕ *and*

---

[10] Caution: This characterization will in general hold only for rates of return of each contingent claim, not for rates of return on *portfolios* of contingent claims.

> the market equilibrium model, can be computed. Compare these computed prices with the prices actually observed in the marketplace. If they are the same, then actual security prices are said to "fully reflect" ϕ. [p. 384]

Although less precise, the implied beliefs of this definition appear similar to consensus beliefs. However, Fama's definition and subsequent use of it suffer from several deficiencies. First, his definition is unnecessarily couched in terms of expected returns. Second, suppose ϕ is fully reflected by his definition and an individual knows only some proper subset of ϕ. He may then assess different date t=0 prices and, although he will be unable to make superior returns relative to ϕ, his mistaken estimate of date t=0 prices will lead him to perceive some securities as over- and undervalued. As a consequence, he may neglect to diversify efficiently. By Fama's definition, an efficient market may coexist with this nonoptimal behavior. Third, unable to draw nontrivial, testable implications from his definition, Fama is forced to supplement it with highly specialized and unrealistic models of equilibrium.

By contrast, the definition developed in this paper arises from within an explicit but quite general equilibrium context. Despite its generality, precise characteristics are derived describing individuals who view the market as efficient (i.e., nonspeculation condition). An important distinction is made between new information and all information. The definition is also linked with the volume of trading. For example, if every individual viewed the market as efficient, there would be no trading at date t=1. In a more general model, with the continuous emergence of new securities and new participants as well as barriers to marketability, the model holds out the promise of distinguishing trading volume for these reasons from trading for speculative purposes. The volume of speculative trading could then be used as a barometer of information efficiency.[11]

Samuelson attempts to justify martingale characterizations of efficiency. He proves the following exceedingly simple theorem:[12]

THEOREM (Fair Game): *If* $P_s=\pi_s$ *and* $P_{s\cdot e}=\pi_{s\cdot e}$ *(all e), then* $P_s=\Sigma_e\pi_e P_{s\cdot e}$.

PROOF:

By the laws of probability, $\pi_s=\Sigma_e\pi_e\pi_{s\cdot e}$ and by assumption $P_s=\pi_s$ and $P_{s\cdot e}=\pi_{s\cdot e}$ (all *e*).

The term P_s, it will be recalled, is the date t=0 price of one unit of consumption received at date t=2 if and only if state *s* occurs. Since the date t=2 price of one unit of consumption received at date t=2 is just 1, π_s may be interpreted as the expected date t=2 price of one unit of consumption received at date t=2 if and only if state *s* occurs, where the expectation is assessed with respect to beliefs held at date t=0. Similarly, given that state *e* has occurred, $P_{s\cdot e}$ is the date t=1 price of one unit of consumption received at date t=2 if and only if state *s* occurs. Given that state *e* has occurred, $\pi_{s\cdot e}$ may be interpreted as the expected date t=2 price of one unit of consumption received at date t=2 if and only if state *s* occurs, where the expectation is assessed with respect to beliefs held at date t=1. Loosely speaking, then, the fair game theorem says: *If the price of a security at every date always equals its expected price at some terminal date, then its price at every date equals its expected price at any future date prior to the*

---

[11] David Downes and Thomas Dyckman, pp. 314–16, offer a less specific but similar suggestion.

[12] Samuelson actually proves a more general version that allows for continuous probability distributions, any finite number of dates, and incomplete markets. However, nothing of significance is lost in the more straightforward theorem given here.

terminal date. This stochastic process of price behavior is called a martingale.

The theorem is obvious. Since its assumption ignores time preference and risk aversion,[13] it is not surprising to learn that the date t=0 price of a consumption claim equals its expected date t=1 price. As it stands, the theorem is a trivial characterization of efficiency, or in Samuelson's words, "properly anticipated prices." Possibly realizing this, Samuelson generalizes the result to allow for positive risk-free interest and risk aversion:

COROLLARY: *If* $P_s=\lambda_{1s}^{-1}\lambda_{2s}^{-1}\pi_s$ *and* $P_{s\cdot e}=\lambda_{2s}^{-1}\pi_{s\cdot e}$ *(all e), then* $P_s=\lambda_{1s}^{-1}\Sigma_e\pi_e P_{s\cdot e}$.

λ_{1s} and λ_{2s} are time and risk-adjusted discount rates that may be different for different consumption claims (i.e., depend on state *s*), but that are ***independent of state e***. Indeed, in this lies the content of the theorem, since if λ_{2s}^{-1} in the second equality were replaced by $\lambda_{2s\cdot e}^{-1}$, the assumption of the corollary would be vacuously true. Examination of the proof of the fair game theorem provides an immediate proof of this generalization.

What is the actual content of these results and how are they related to the definition of efficiency provided in this paper? In view of the restrictive equilibrium implications of the fair game assumptions, we will turn more hopefully to Samuelson's generalization. However, in the context of nonspeculative beliefs (and, hence, consensus or homogeneous beliefs), a significant inconsistency emerges. By the assumption of his corollary, $\pi_s/P_s=\lambda_{1s}\lambda_{2s}$ and $\pi_{s\cdot e}/P_{s\cdot e}=\lambda_{2s}$ (all *e*). Substituting these relationships into the nonspeculation condition $\pi_s/P_s=(\pi_e\pi_{s\cdot e})/(P_e P_{s\cdot e})$ (all *e*), we derive $\pi_e/P_e=\lambda_{1s}$ (all *e*). This not only means π_e/P_e must be independent of *e*, but also that λ_{1s} must be independent of *s*. Indeed, by summing over *e*, $\lambda_{1s}=1/(\Sigma_e P_e)$. Interpreting this verbally, all claims to consumption at date t=2 have the same risk-adjusted discount rate between dates t=0 and t=1 equal to one plus the risk-free rate. In effect, despite Samuelson's attempt to generalize to risk-adjusted discount rates, an individual with nonspeculative (or consensus, or homogeneous) beliefs will use the risk-free rate, not adjusting for risk.

As Samuelson asks at the end of his paper:

> I have not here discussed where the basic probability distributions are supposed to come from. In whose minds are they ex ante? . . . Are they supposed to belong to the market as a whole? And what does that mean? Are they supposed to belong to the "representative individual," and who is he? . . . This paper has not attempted to pronounce on these interesting questions. [pp. 48–49]

While the present paper has not unveiled this mystery man, if securities are not all to be discounted at the risk-free rate, he cannot have homogeneous, consensus, or even nonspeculative beliefs. In short, he may not be an economically interesting individual.

Another tempting definition is to associate with information efficiency the holding of (possibly levered) value-weighted balanced portfolios. However, we know from David Cass and Stiglitz that even in a static homogeneous economy, individuals will not generally desire to hold (possibly levered) miniatures of the market portfolio. Yet, by any meaningful definition, homogeneous belief is surely a sufficient condition for information efficiency.

"Intrinsic value" is another recurrent phrase associated with efficiency. Clearly, nothing has intrinsic value apart from the resources, tastes, and beliefs of all individuals in the economy. However, taking a more charitable view toward intrinsic value, perhaps it refers to valuations based on the pool of all available information. In other words, *intrinsic values are those equilibrium prices set as if each individual publicized all his information.* In this "as if" economy, all individuals would have homogeneous beliefs. If *these as if* homogeneous beliefs happen to coincide with the actual consensus beliefs, only then, by this definition, will the actual market be efficient. Although this definition is perhaps closest in spirit to the implicit definitions used in most of the empirical literature, it still suffers from the coexistence of nonoptimal speculative trading. That is, just because equilibrium prices are set as if each individual publicized all his information does not mean that any individual bases his choices on the pooled set of available information.

---

[13] Alternatively, it ignores time preference and presumes a riskless economy in which risky securities may exist as long as, through offsetting effects, aggregate consumption is certain.

V. Limitations

The chief difficulty with the concept of information efficiency developed in this paper has been the absence of transactions costs. Without these costs, in a heterogeneous economy, complete markets are a natural evolution of the structure of exchange opportunities. At a deeper level, the choice, cost, and the communication of information which creates transactions cost has not received even implicit attention.

It is useful to distinguish between two types of information about security prices —information about the *supply* of aggregate consumption and information about the *demand* for it. The dynamic optimization problem envisaged here requires a considerable degree of forethought: an individual must not only choose (C_0, $\{\hat{C}_e\}$, $\{\hat{C}_{s \cdot e}\}$), but also decide in advance at date t=0 how he will revise these provisional choices at date t=1 (choose (C_e, $\{C_{s \cdot e}\}$) for all states e). In this planning process, at date t=0 the individual utilizes date t=1 equilibrium state conditional prices even before the date t=1 market convenes! In effect, we have assumed that given the resolution of uncertainty surrounding the aggregate supply of consumption, demand conditions and hence prices are known with certainty.[14] In a more general setting, even if supply uncertainty were resolved, lacking information about the resources, beliefs, and tastes of other individuals, an individual could not forecast demand and hence prices with certainty. Unfortunately, for issues examined in this paper, absence of demand uncertainty is particularly objectionable since it cavalierly ignores the Keynesian or psychological view of the securities market in which speculative bubbles are a possibility.[15]

While the reduction of demand uncertainty motivates transactions costs, supply uncertainty also motivates the acquisition of information. The model developed in this paper contained no explicit analysis of its choice—beliefs were taken as data. Moreover, although different individuals had different beliefs, this information was implicitly assumed to be costless. With explicit consideration of productive choice and delegation of authority to managers of firms, supply uncertainty would become more complex. Individuals would not only be uncertain about the outcomes of "natural processes," but also about the behavior of managers. In turn, this additional cause of uncertainty would derive from two sources: uncertainty about their reported production choices and uncertainty about discrepancies between their actual and reported choices.

---

[14] Actually, this statement only holds for results, such as the identification of consensus beliefs, which require a market equilibrium setting. The identification of nonspeculative beliefs requires only a model of individual behavior in which uncertainty about future prices can derive from both supply and demand conditions.

[15] This distinction between supply and demand uncertainty would seem to be at the root of the separation of so-called "fundamental" and "technical" approaches to security analysis.

A theoretical exploration of the meaning of the phrase "security prices fully reflect information," in the presence of the choice, cost, and communication of information potentially capable of reducing demand and supply uncertainty, must await another opportunity.

The Consumption Function in a Developing Economy and The Italian Experience

By F. MODIGLIANI AND E. TARANTELLI*

The many models that have been proposed since J. M. Keynes' *General Theory* to explain aggregate consumption and saving have been largely developed with reference to mature, western-type, capitalistic economies. This paper examines, in the first place, how well the various models can account for the behavior of saving in a country undergoing rapid development such as Italy in the postwar period. It next reviews a number of "stylized facts" characterizing the process of development, which, in turn, lead to some needed extensions of existing models.

Our main conclusions can be summarized as follows: 1) All major models, starting from the standard textbook consumption function, provide a reasonably good approximation to the behavior of aggregate consumption in the two decades terminating in the early 1970's. At the same time, the successive vintages of the consumption function do yield some improvements. 2) On the whole, the model that appears to provide the most fruitful framework for a consistent understanding of saving behavior, both at the aggregate and the cross-sectional level, is the life cycle hypothesis of consumption (*LCH*) in its more general form, according to which consumption depends on expected income from labor, wealth, and "permanent" income from wealth. 3) However, even this model needs to be modified along Ricardian-Marxian lines to take account of the consumption behavior of the reserve army of the structurally unemployed, which gradually dwindles in the process of development. 4) Our other major result is to provide overwhelming evidence against the standard Kaldorian two-casts parable of hard-pressed workers consuming all and plush capitalists saving almost all, which so far had been held to provide the most satisfactory explanation of the behavior of aggregate saving in Italy. 5) The crucial piece of evidence supporting the proposition stated in (4) is that the consumption coefficient of "expected" profits is not only larger than that of expected labor income, but is in fact larger than one. This result is not merely inconsistent with the Kaldorian hypothesis but altogether uninterpretable in that framework, whereas it is shown to be fully consistent with the implications of the life cycle model. In this model every household is typically both a worker and a recipient of property income during at least some phase of the life cycle and may be expected to respond differently to these two differing sources of income. 6) It is shown that the coefficient measuring the response of consumption to property income cannot be interpreted as a marginal propensity in the customary sense of the word and reflects, at least in part, the degree of substitution between current and future consumption in the utility theoretic sense.

* Massachusetts Institute of Technology. Some of the equations proposed here are part of the Econometric Model of the Bank of Italy, which partly supported the present work, and whose aid is gratefully acknowledged. We also wish to thank the National Bureau of Economic Research for use of the TROLL System for Applied Econometric Research, and, finally, to express our appreciation to many colleagues of the Research Division of the Bank of Italy for useful discussion and advice. In particular Bruno Sitzia contributed importantly to the development of the tests discussed in Section IV. The main issues examined in this paper are dealt with in greater detail in our forthcoming book.

I. The "Old Theories," the "Permanent Income" Hypothesis, and the Kaldorian Model

The first conclusion listed in the introduction can be readily established by an inspection of Table 1 which shows the result obtained by fitting to Italian aggregate data the standard Keynesian model (equation 1), the Duesenberry-Modigliani (D-M) 1949 model in its original form (equation 2), and the Tillman Brown-Tom Davis (B-D) version (equation 3). Strictly speaking, the explanatory variable called for by the D-M model is, besides current income, the highest previous income. But, in the case of Italy, as for any continuously growing economy, the highest previous income reduces to lagged income. Similarly, for the B-D model the highest previous consumption coincides with lagged consumption.

For every model, two alternative estimates of the parameters are provided, first using the linear form (equations labeled L),

TABLE 1—ESTIMATES OF PARAMETERS OF CONSUMPTION FUNCTION: ITALY, 1952–70

Consumption Function		Coefficients of						
		Constant	Y	Y_{-1}	C_{-1}	$P(Y/YN)$	$S.E.$	$D.W.$
Elementary Keynes	1L	1355.4	.78				322.3	1.41
		(246.8)	(.011)					
	1R	1687.7	.76				.0154	.98
		(224.9)	(.012)					
Duesenberry Modigliani (D-M)	2L	1254.3	.23	.58			250.3	1.23
		(193.8)	(.16)	(.17)				
	2R	1571.5	.33	.46			.0134	.95
		(200.5)	(.17)	(.18)				
Brown-Davis Friedman (B-D)	3L	499.1	.40		.52		260.9	1.66
		(337.1)	(.12)		(.17)			
	3R	648.5	.37		.55		.0122	1.32
		(356.9)	(.12)		(.16)			
Kaldor (KH)	4L	2927.2	1.02			−.70	245.1	1.17
		(468.5)	(.068)			(.19)		
	4R	3448.9	1.06			−.83	.0106	1.07
		(421.5)	(.067)			(.19)		

Note: The figure in parentheses underneath each coefficient is the standard error of the coefficient. $S.E.$ and $D.W.$ denote, respectively, the standard error of the regression and the Durbin-Watson coefficient. C, Y, and $P(Y/YN)$ denote, respectively, total private domestic consumption, total disposable income, and "independent labor income" (national income less wages and salaries) multiplied by the ratio of disposable to net national income. All variables were measured in billions of lire at 1963 prices. (Over the period of analysis, 1 billion lire was roughly equivalent to 1.6 million dollars at the official exchange rate.) The average value for C in the period under consideration was 18,340 billions of lire. Dividing $S.E.$ by this value one can calculate the percentage standard error of the linear equations. For the equations expressed in ratio form (R), the dependent variable is C/Y, and $S.E.$ gives the root mean square error as a percentage of income. Disposable income was defined as national income plus government transfers minus personal and corporate income taxes. Note that this definition differs from the standard one because it includes undistributed corporate profits.

and second dividing both sides of the equation by income (equations labeled R). This alternative estimate is provided because, over the period of observation, both consumption and income have grown very substantially (roughly by a factor of three) and, therefore, the error term may be more nearly homoscedastic in the ratio than in the linear form. Note also that the models tested would generally call for the use of per capita rather than aggregate real data. However, since population has changed very little over the period of observation, we find it convenient to use aggregate data, expressed in real terms using as a deflator the implicit price index of private domestic consumption. It is apparent that even the standard Keynesian function fits well, as its standard error is well below 2 percent of consumption (see the footnote to Table 1). The next two models yield appreciably smaller standard errors. Note also that in terms of fit, the B-D model is an improvement over the D-M model only in its ratio version. However, it does yield a much smaller and barely significant constant term which accords better with the specification of the hypothesis and the nowadays widely held view that the saving ratio should, in the long run, be independent of the level of income (though not of its rate of growth). Note that in both the D-M and B-D equations the coefficient of the lagged variable is distinctly larger than that of the current variable, implying a long lag in the response of consumption which will play an important role in what follows.

The three models discussed so far belong to the empirically oriented tradition of the early post-Keynesian period, that is, they belong to what has since come to be known, in Michael Farrell's words, as the "old theories of the consumption function." However, equation 3 can also be interpreted as providing a test of one version of the "new theories," namely, Milton Friedman's Permanent Income Hypothesis. As is well known, Friedman suggested that permanent income could be approximated by an exponentially weighted average of past incomes, a formulation which, making use of the L. M. Koyck transformation, leads to an autoregressive equation of the form of equation 3.

Equation 4 provides a test of Nicholas Kaldor's hypothesis (hereafter KH) that the propensity to consume of the recipients of property income, the "capitalists," is significantly lower than that of the recipients of labor income, the "workers." Denoting by a_p the propensity to consume out of net of tax property income P^*, and by a_w the corresponding propensity for wage income W^*, KH can be stated as

$$(4) \qquad C = a_w W^* + a_p P^*, \quad a_p < a_w$$

Recalling that $W^* + P^* = Y$, (4) can be rewritten in ratio form as

$$(4') \qquad C/Y = a_w + (a_p - a_w)P^*/Y$$

which shows that the saving ratio $S/Y = 1 - C/Y$ does not depend on income as such, but instead on income distribution, P^*/Y.

The national income accounts do not provide explicit measures of W^* and P^*, i.e., labor and property income net of taxes, but provide only estimates of *dependent* labor income (wages and salaries) and of other incomes (with various breakdowns) gross of personal taxes. These variables have, therefore, been approximated by relying on the assumption that the ratio between P^* and W^* and the corresponding measures gross of taxes, P and W, are approximately equal, i.e., that the incidence of taxes is roughly the same on the two sources of income. This assumption, though risky, finds some justification in the tax structure of the country taking into account the phenomenon of widespread tax evasion, especially on property income. Thus,

$$\frac{P^*}{P} \simeq \frac{W^*}{W} \simeq \frac{Y}{YN} \tag{5}$$

where YN is "real" (net) national income. From (4) and (5) and since $W+P=YN$, one derives

$$C = (a_p - a_w)P\frac{Y}{YN} + a_wY \tag{6}$$

Following studies made by A. Niccoli and S. Vinci, for the Bank of Italy in 1970, testing KH for the Italian economy, a constant was added to (6) even though it presumably should be close to zero. It is apparent from equation 4 that both the scaled and unscaled equations fit the data somewhat better than the previous models, though in both equations the Durbin-Watson statistic still indicates the existence of substantial positive serial correlation.

These results, and similar ones obtained by others, have often been interpreted as providing strong support for the Kaldorian model. They imply, in fact, a marginal propensity to consume out of labor income of 1.02 to 1.06, and corresponding propensities to consume out of property income of only .32 to .23. Yet these estimates show a number of grave inconsistencies and dubious implications. First, the estimated marginal propensity to consume out of wage income appears unreasonably high. Second, the estimated marginal propensity to consume for nonlabor income as low as .23—i.e., four to five times lower than that out of wages—is rather dubious. It is, in fact, glaringly inconsistent with the results of budget studies.

One of the most complete and comprehensive series of these studies for the Italian economy, conducted by A. Ulizzi for the Bank of Italy, classifies families into two groups, dependent workers and the self-employed, which correspond to those underlying the National Income classification of dependent and independent workers. The behavior of savings within each class is very much in line with what one would expect on the basis of the permanent income or life cycle hypothesis of savings. Specifically, for the dependent families whose income may be presumed to be relatively stable over time, the proportion of income saved is roughly independent of income and around 7 to 8 percent (see Ulizzi, p. 424, Table 3.4 and Graph 2), at least for incomes above 1 million lire. (Even for income recipients below 1 million, which undoubtedly contain a sizable proportion of the transiently poor, saving is positive and around 3 percent.) For the group as a whole, average saving amounts to 5.8 percent, which is clearly inconsistent with the results given above implying a *negative* average propensity to save of 2 to 6 percent. On the other hand, for the self-employed, including farmers and other entrepreneurs whose income is notoriously subject to wide short-run fluctuations, the saving ratio tends to rise markedly with income, being negative for incomes up to 2 million lire and increasingly positive for the remaining two groups. This is precisely what one would expect for a group whose income is uncertain and fluctuating, if consumption depends on "permanent income" (Friedman), or "life resources" (Modigliani-Ando, 1960). For such groups, a better estimate of the average and marginal propensity to save is provided by the sample average which turns out to be 8.4 percent.[1] These results indicate a roughly similar average propensity to consume for the two groups, and contradict those suggested by the Kaldorian equation (4).

---

[1] These figures were kindly provided by Ulizzi and are consistent with the results shown in Table 3.4 of his work. In his definition, the self-employed include workers in agriculture and other sectors, entrepreneurs, and professionals. Dependent labor includes wage earners and employees. Pensioners are excluded from both definitions of income. This, together with other characteristics of the sampling procedure adopted, leads to an underestimate of the average propensity to save which should not, however, appreciably affect the magnitude of the propensities to save relative to each other.

Finally, in equation (4), the constant term is by far the highest of all the estimates presented so far and is statistically highly significant. This result plays havoc with the well-known Kaldorian theory of income distribution. Indeed, adding a constant a to (4), the Kaldorian saving function can be written as: $S=(1-a_w)W^*+(1-a_p)P^*-a=I$, where I denotes investment. Substituting for W^* from the identity $Y=W^*+P^*$ and solving for P^*, the share of profits implied by the Kaldorian theory of income distribution can be written as:

$$\frac{P^*}{Y}=\frac{1}{(a_w-a_p)}\left[\frac{I}{Y}-(1-a_w)+\frac{a}{Y}\right]$$

which, in turn, implies that given a_p and a_w, and for a given investment ratio, the long-run share of profits is a decreasing function of income and not a constant as implied by the theory. (See Kaldor, p. 229.)

It is the contention of this paper that the improbable estimates of the parameters of (6) result from the failure to take into account a number of fundamental characteristics of a developing economy, like Italy's, in the period under consideration and their implications for an understanding of consumption behavior. These characteristics are reviewed below.

II. Some "Stylized Facts"

A

First, it is wrong to identify dependent labor income with Kaldorian labor income and the remaining income with profits, because of the well-known fact that in an undeveloped economy such as Italy's in the early postwar years, the *independent* labor pool contained a substantial portion of self-employed, of marginally employed, and/or of "disguised" unemployed. Indeed, in 1951, the number of supposedly "capitalist" independent workers amounted to 7,700,000 on a total labor force of some 17 million.[2] Furthermore, in the early 1950's, the per capita income of the independent workers was quite close to that of the dependent workers as shown by Figure 1, which traces the behavior of the ratio of per capita income of dependent workers to that of the independent workers. Thus, in 1951, per capita dependent labor income equalled $720 as against only $890 for per capita "profits." (In other words, according to the conventional definition, the capitalists would have shared the misery of the workers!)

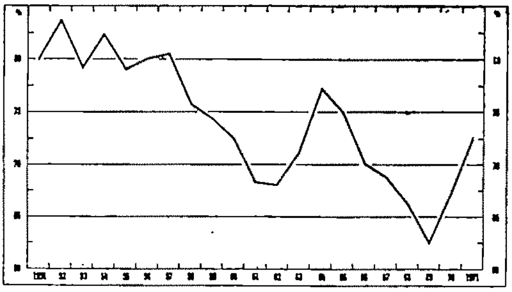

Figure 1. Ratio Between Per Capita Dependent Labor Income and Other Incomes

As also indicated by the budget studies mentioned previously, these small differences in the average per capita earnings of the two groups cannot account for the extreme gap in the two propensities to consume suggested by the "naive" Kaldorian equation. The narrow differences in earnings[3] suggest, in fact, that there has been and still is a whole group, conventionally included in the independent labor category, for which average per capita income and saving behavior are likely to be roughly similar to those of the dependent labor group.[4]

---

[2] We have been told that in some parts of the south, this group of people is jokingly referred to as "gli industriali, perchè si industriano" which can be roughly paraphrased as "the managers, because they manage." For a stimulating and enlightening discussion of the "class composition" of the Italian labor force and its development in time, see P. Sylos-Labini (1972).

[3] In 1971, per capita dependent "labor income" averaged $4000, as against only $5400 for per capita "profits." See Tarantelli (1973a, b).

B

The measured share of wages and salaries as a proportion of net national income has increased remarkably in the period under consideration. As the Annual Report of the Bank of Italy for 1971 has shown,[5] this change does not arise from an increase in the average per capita earnings of this group relative to the income of independent labor: the ratio between the two has, in fact, fallen, as shown by Figure 1. It arises instead from the increase in the share of dependent labor in the total labor force, as one might expect for a developing economy,[6] as a consequence of two major features of development: a) the continuous flow of marginal and low-income independent workers into the dependent labor pool; b) the substantial fall, up to the beginning of the 1960's, in the number of structurally unemployed who were also largely absorbed into the dependent labor pool. The report of the Bank of Italy also suggests that once the data are "purged" of the bias due to the change in the composition of employment, the long-run trend in favor of wages shown by Figure 2 disappears. The "corrected" distribution of income shows modest cyclical fluctuations around a constant, as shown by Figure 3.

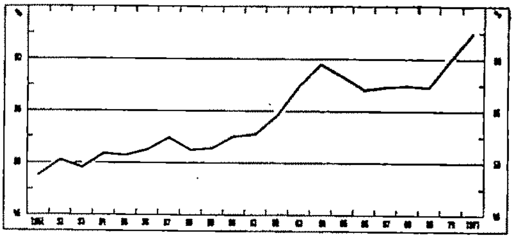

FIGURE 2. SHARE OF WAGES AS A PROPORTION OF NET NATIONAL INCOME

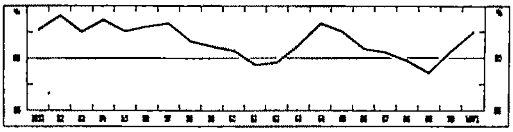

FIGURE 3. WAGE SHARE "CORRECTED" FOR THE VARIATIONS IN THE COMPOSITION OF EMPLOYMENT

C

It seems plausible to assume, à la Karl Marx, that the marginal and average propensity to consume of the structurally unemployed in a developing economy equals one. This group is a receiver of dependent and independent labor income from occasional gainful employment and from low earnings in unrecorded activities and of transfer income from the gainfully employed.

Because of the higher propensity to consume of the structurally unemployed, one would expect that in a developing economy, the gradual absorption of this group into the labor pool would involve a corresponding fall in the average propensity to consume of the system as a whole.[7] This presumption is fully verified by the Italian postwar experience. As Figure 4 shows, the average propensity to consume has substantially fallen from 1951 to the beginning of the 1960's, while following a cyclical pattern thereafter. Figure 4 also shows the remarkable fall in the number of the structurally unemployed in the 1950's. The parallelism of the two series in the graph would seem to support the

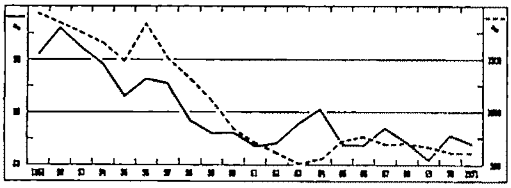
---

[4] Along similar lines, Sylos-Labini (1967) suggested that "dependent workers have a propensity to consume near to unity, that the independent workers receive an income that moves together with that of the dependent ones and have a propensity similarly high" (p. 360).

[5] See Banca d'Italia (1971, p. 147).

[6] By 1971, the number of independent workers had shrunk from 7.7 to 5.7 million, representing 30 percent of the labor force, as against 46 percent in 1915.

[7] For earlier interest in this evidence, see F. Di Fenizio and A. Graziani.



– – – – – – Number of Unemployed (in thousands)
———————— Average Propensity to Consume

FIGURE 4

Ricardian-Marxism hypothesis proposed above.[8]

These "stylized facts" suggest two major modifications of (6). First, following the procedure of the Bank of Italy, total labor income is estimated as the sum of dependent labor income and an ***imputed*** labor income of the ***independent*** workers measuring, in essence, their "opportunity cost" of self-employment. This opportunity cost is assumed to equal, on the average, the average wage income of dependent workers W/LD, where LD stands for the number of dependent workers. Thus, letting LL denote total employment, our measure of the "corrected net of tax labor income" becomes $(W/LD)LL(Y/YN)$.[9] Second, one needs to account for subsistence consumption of the dwindling army of the unemployed, U.[10] Thus, equation (6) must be modified to:

$$C = a_w\hat{W} + a_p\hat{P} + a_uU \tag{7}$$

where U denotes the number of unemployed and

$$\hat{W} = \frac{W}{LD}LL\frac{Y}{YN}; \quad \hat{P} = Y - \hat{W} \tag{7'}$$

Equation (7) can be used directly for linear estimation, and the coefficients a_p and a_w of $\hat{P}$ and $\hat{W}$ provide direct estimates of the Kaldorian marginal propensity to consume (MPC) of the capitalists and the rest of the population, respectively. For ratio estimation, in order to preserve the same dependent variable used in the test of the other models, namely C/Y, it is necessary to perform a transformation by adding and subtracting $a_p\hat{W}$, which yields

$$\frac{C}{Y} = a_p + (a_w - a_p)\frac{\hat{W}}{Y} + a_u\frac{U}{Y} \tag{7''}$$

III. Empirical Test of the Modified Kaldorian Model

Empirical tests of equations (7) and

---

[8] It seems worth noting that the recognition of the above *stylized facts* can readily account for the relatively good mechanical fit of the naive Kaldorian equation 4 and some of its properties. The large constant term in equations 4L and 4R of Table 1 mechanically accounts for the higher than average and falling average propensity to consume up to the beginning of the 1960's. To be sure, this constant would imply, on the other hand, a fall in the average propensity to consume also for the rest of the period under consideration, contrary to what has in fact happened. Equations 4L and 4R account for this pattern by assigning an unreasonably high weight to the share of wages, which as can be seen from Figure 2, increased but little up to 1960 (from .49 to .52), but substantially in the second half of the period (from .52 to .61), thus offsetting the depressing effect of the constant term.

[9] This approach assumes that there is no appreciable number of "pure capitalists." This conjecture is supported by the estimates produced by Sylos-Labini (1972). In any event, we have also computed an alternative estimate of labor income assuming that pure capitalists represented 30 percent of employment, the proportion of self-employed at the close of the sample period. To this end, the average income of dependent labor was imputed to only 70 percent of the labor force. This alternative was used in all the tests reported below, but since in no case did it lead to qualitatively different conclusions, the results (and their implications for shares of the dependent labor force included between these two alternatives) are omitted here, though they can be found in the authors' forthcoming book. The measure used here also coincides with that discussed in Tarantelli (1970). See also Tarantelli (1973a,b).

[10] As shown in the more extensive version of our model cited earlier, the unemployment component should in principle distinguish between structural and cyclical unemployment and account for the variations of the average income per capita of dependent labor. See also the same reference for a discussion of the issues involved and for a detailed derivation of equation (7) from the aggregation of the relevant income subgroups. The distinction between structural and cyclical unemployment is also elaborated by the authors (1973).

(7″) are reported in the equations labeled 1 and 2, Table 2. In equation 1, we omit the unemployment variable, mainly for purposes of comparison with the standard Kaldorian equation reported in Table 1, 4*L* and 4*R*. While the estimated coefficients have the expected sign, all equations give a somewhat poorer fit than the equations of Table 1. The estimated *MPC* out of wages falls to a more reasonable .85, while that out of profits is unaffected. But the constant terms remain highly significant in all cases.[11]

The addition of the variable relating to structural unemployment in equation 2 improves substantially the general characteristics of the equations. The constant becomes of negligible magnitude and statistically insignificant, implying a long-run consumption-income ratio independent of income for given distributive shares. As a result, if the constant term is suppressed as is shown in equations 3*L* and 3*R*, the coefficients of the variables are essentially unaffected and the standard error adjusted for degrees of freedom is actually reduced. Similar results were found to hold also for the other versions of the model reported in Table 2. In view of this, and since a priori considerations suggested that the constant term should in fact be zero, further results are reported only for equations estimated constraining the constant term to be zero.

The order of magnitude of the point estimates of the coefficient of U implies an average "subsistence minimum" slightly above half a million lire ($800) which is somewhat high, but not altogether beyond reason. However, the estimated marginal propensity of "capitalists" remains rather small, .42, still only half as large as a_w. Thus the results of row 3 would seem to provide strong support for Kaldor's model.

But these equations still suffer from one serious shortcoming, namely that they make no allowance for the possibility of a gradual response of consumption to income, especially property income, as suggested by a number of earlier studies on this topic and by previous considerations. This could, in part at least, explain the relatively low *t*-ratio of property income, and the autocorrelations of residuals in equation 3 of Table 2.

An operationally simple approach to allow for this possibility is to amend (7) as follows

$$(8)\ C = a_w\hat{W} + a_p\hat{P} + a_p'\hat{P}_{-1} + a_uU + dC_{-1}$$

This formulation allows for consumption to respond with an exponentially distributed lag to past labor income, while the response to profits can be expressed as the sum of *two* distributed lags, which allows for the possibility of a longer average lag for this variable. In (8), a_w and a_p measure the short-run *MPC* out of wages and profits, respectively, while the corresponding long-run propensities are given by

$$\hat{a}_w = \frac{a_w}{1-d}; \qquad \hat{a}_\pi = \frac{a_p + a_p'}{1-d}$$

The tests for equation (8) in both linear and ratio form are shown in Table 2 as equations 4*L* and 4*R*.

The results of the linear form confirm that the short-run *MPC* for labor income (around .60) is much larger than that for current profit, around .22. However, the long-run *MPC* out of labor income (.8) is now *lower* than that out of property income which comes to .90. If the coefficients are estimated in ratio form, the results are even more striking: $\hat{a}_w = .8$, $\hat{a}_\pi = 1$. Clearly, these results are entirely inconsistent with the Kaldorian hypothesis—indeed they

---

[11] The estimates of *LD* and *LL* were calculated in full-time equivalent employees. The number of full-time equivalent employees is estimated by adding to the number of full-time employees one-third of so-called "marginal employees," essentially defined as those with less than 32 hours worked per week (even though they would be willing to work longer hours). 5*R*		.68	.41 (3.2)	.68 (9.8)			.7	1.48 (4.2)	.0086	1.77

Note: In the ratio form, the coefficient a_w is obtained by fitting (8) to the data and then adding the coefficient of W/Y to the constant term. For this reason, the regression program does not provide an explicit value of the standard error of a_w, although such a standard error could be computed from the variance-covariance matrix of the errors of the coefficients. We have felt it unnecessary to perform this computation since the t-ratio of a_w is uniformly very large, and of the same order of magnitude as that reported for the linear form. The values in parentheses below the coefficients indicate t-ratios for the corresponding estimates.

are impossible to interpret in that framework.[12]

To be sure, hypothesis (8) is rather restrictive as to possible shapes of the distributed lag for the two components, though the result, implying a very rapid decay for the weights of past labor income, and hump-shaped weights, rising at first then decaying more slowly for $\hat{P}_{-1}$, are certainly consistent with what one might expect a priori. In addition, the previous estimates have one further econometric shortcoming in that the equation is estimated in autoregressive form, which could in principle bias the point estimates of the lagged dependent variables. As an alternative, we assumed that expected labor income could be identified with the current value $\hat{W}$, especially since the possible effects of cyclical variations in employment are taken into account through the unemployment variable. We relied on the specification,

$$(9) \quad C = a_w\hat{W} + a_p\hat{P} + \gamma L(\hat{P}_{-1}) + a_u U$$

in which L is an exponentially distributed lag beginning with $\hat{P}_{-1}$.[13] The rate of decay λ was estimated by scanning over the range $0<\lambda<1$ for the value minimizing the residual variance.[14]

---

[12] The approach of equation (8) was first pursued in a yet unpublished study of Bruno Sitzia. He also pursued some alternative methods of estimating $\hat{a}_r$ all of which confirmed that this coefficient is as large or larger than $\hat{a}_w$. His valuable contribution as well as his advice in designing the tests reported here are gratefully acknowledged.

[13] The Koyck variable for the first year in the sample was obtained by extrapolating backward the positive trend of the profit variable estimated for the first five years (1951–55), until it tended to vanish, and by applying the Koyck transformation to the sample.

[14] As a check, we estimated separate exponentially distributed lags for W; whenever this procedure was tried, the estimate of λ for this component turned out to be around 1 while the estimate of λ for the $\hat{P}$ component was basically unchanged.

From the tests of (9) and of its ratio form reported in equation 5,[15] Table 2, it appears that the distributed lag makes a substantial contribution to the explanation of C; the value of λ in both linear and ratio form indicates a rather slow rate of decay, much as one would expect in view of the short-run variability of profits. The coefficient of current profit is again only half as large as that of labor income. But when we add to it the very high coefficient of lagged profits, we arrive at an estimate of a_p not merely higher than a_w, but actually between 1.5 and 2. This is likely to be a shocking and inadmissible result for those who try to interpret $\hat{a}_\pi$ in the Kaldorian framework as the *MPC* out of property income. As we shall see presently, it is perfectly consistent with the *LCH* framework, which implies an altogether different interpretation.[16] The coefficient of unemployment is again highly significant,[17] though somewhat high, probably reflecting some upward bias.[18]

To summarize, the Kaldorian-type equation of equations 4 and 5 appear to fit quite well the data of the postwar Italian experience. They also yield a sensible estimate of the *MPC* out of labor income and of the effect of structural unemployment. At the same time, the estimated coefficient of profits is of an order of magnitude which is altogether inconsistent with the Kaldorian hypothesis. Hence, if we are to accept this equation as a valid description of saving behavior, it must be on the basis of a framework other than the Kaldorian one. In the following sections, we shall show that such a framework can be provided by the life cycle hypothesis of saving, once the hypothesis is generalized to take into account the stylized facts of development discussed earlier.

IV. The Life Cycle Hypothesis

The life cycle hypothesis (*LCH*), (see Modigliani and Richard Brumberg, 1954), rests on the proposition that the consumption of the representative household reflects the endeavor to achieve the preferred allocation of its life resources to consumption over the life cycle. Together with some further simplifying assumptions, this hypothesis leads to an aggregate consumption function linear in current and expected labor income, YL and YL^e, and in net worth A:

$$\begin{aligned} C &= a'YL + a''YL^e + \delta A \\ &\simeq \alpha YL + \delta A \end{aligned} \tag{10}$$

where α and δ in principle depend on the rate of growth of income and the rate of return on assets.

There are serious problems in attempting to test an equation of the form (10) for Italy since at present there is no available estimate of total consumers' net worth at market prices. The closest proxy available for the period of observation is an estimate of the aggregate value of financial wealth held by households. This estimate,[19] denoted by A^*, falls considerably short of total consumers' net worth A, omitting such items as equity in noncorporate business, and in tangibles directly held by households—residential real estate, land, and the stock of durable goods. Judging from American experience and other very indirect evidence, one might guess that on the average, over the relevant postwar period, A^* has been in the order of one-half to two-thirds of A; but this is no more than an educated guess and, furthermore, this figure might well have fluctuated and also has probably tended to increase in the process of development with the spread of financial intermediation.

---

[15] For the ratio estimate, (9) was transformed to $C/Y = a_p + (a_w - a_p)\hat{W}/Y + \gamma L(P_{-1})/Y + a_u U/Y$.

[16] Similar results were found to hold in the course of the first stage of this research by Tarantelli (1973), even though it was then chosen to give only regression estimates in the neighborhood of the value minimizing the standard error sufficient to reject the Kaldorian hypothesis. An analysis of the results reported here would have implied a framework totally different from the Kaldorian model (see Tarantelli, 1973, note 44, p. 133), and which will be developed in the following pages.

[17] Following similar lines, T. Ter-Minassian, in a yet unpublished study, tested the hypothesis according to which the average propensity to consume for durables should tend to increase as the structural unemployment army decreases. Some preliminary results would also seem to support the symmetrical hypothesis of a fall in the average propensity to consume foodstuffs.

[18] The upward bias may result from our failure to separate the effect of structural and cyclical unemployment, as would be called for by our model. This separation, however, must await the availability of quarterly data, which would provide additional degrees of freedom and thereby also enable us to allow for a subsistence minimum varying as an increasing function of per capita earnings.

[19] Data were based on F. Cotula and M. Caron.

As for the variable YL, since what is conceptually needed is a measure of income from "human capital" which clearly includes not only wages and salaries but also the imputed labor income of farmers and other self-employed (independent) workers, we used the same measure $\hat{W}$, used for the Kaldorian test. Further, in testing the *LCH* equation (10) for a developing country like Italy, we must again allow for the effect of structural and cyclical unemployment. Considerations entirely analogous to those set out in connection with the test of the Kaldorian hypothesis led us to approximate this effect by adding the number of unemployed U to the right-hand side of (10). Thus, the equation finally tested was:

$$C = \alpha\hat{W} + \delta A^* + \beta U \tag{10'}$$

where $\hat{W}$ is defined by equation (7′) and A^* denotes financial wealth deflated, like C and W, by the implicit price deflator for private domestic consumption.

A test of this equation in both linear and ratio form is reported in equations $1L$ and $1R$ of Table 3. The results are rather interesting considering the shortcomings of the data. In the first place, in both cases the equation fits the data appreciably better than any of the "old theories" or, for that matter, the permanent income model tested in Table 1.[20] Second, the coefficient of wealth is highly significant and its value is of the right order of magnitude. The fact that it is somewhat larger than that observed for the United States (.06 ± .02, see Albert Ando and Modigliani, 1963) is to be expected since A^* underestimates private net worth A. In fact, it is probably somewhat on the low side, though this too could be accounted for by the attenuation effect resulting from the "noise" in A^* as a measure of A. Similarly, the coefficient of α is somewhat on the high side but again not by a large factor. One may suspect that the underestimate in the coefficient of A^*, because of attenuation, is absorbed in part by the coefficient of YL and in part by that of U, which is again highly significant but clearly on the high side.[21]

V. The *LCH* versus the Kaldorian Hypothesis

In the test of (10′), as in similar tests for the United States and other countries, it was assumed that the coefficients α and δ could be taken as constant in time. Actually, as mentioned earlier, both coefficients should in principle depend also on r, the rate of return on assets, as was confirmed

---

[20] The reader might wonder to what extent the superiority of the *LCH* results of equation 1, Table 3, over those of the old theories of Table 1 is due to the inclusion of the unemployment variable rather than to the replacement of income with labor income and wealth. To answer this question, the variable U has been added to the equations of Table 1, rows 2 and 3. In both cases, the addition of the unemployment variable improved the fit, but the *S.E.* remained substantially higher than in the life cycle test of row 1, Table 3.

[21] In equation 1 as in all the remaining equations (except 3) in Table 3, we report estimates with the constant term constrained to zero. This specification is consistent with the hypothesis, at least if wealth could be measured directly. Some question about the appropriateness of this specification may, however, arise because of the use of A^* as a proxy for A. In any event, when equation (10′) was estimated with a constant term, this term was uniformly insignificant while the other coefficient estimates hardly changed. For a further discussion of possible bias arising from the use of A^*, see the authors (forthcoming).

TABLE 3—ESTIMATES OF PARAMETERS OF CONSUMPTION FUNCTION: ITALY, 1952–70

		Coefficients of									
	Dependent Variable	YL	P	λ	$L(\hat{P}_{-1})$	P^p	A^*	U	Constant	$S.E.$	$D.W.$

by some numerical calculations in the unpublished paper by Modigliani and Brumberg, reported in Ando and Modigliani (1963). However, the nature of this dependence is rather complex. The difficulty here is the familiar one that a rise in r (which should be interpreted here as the long-term *real* rate of return, since variations in the short-term rate around a stable long-run level would have negligible effects), labor income constant, affects the life profile of consumption both through an income effect, tending to raise consumption at all ages, and a substitution effect tending to shift consumption away from the present and toward a later age. In the case of current consumption these two effects go against each other and the net effect cannot be ascertained unless one is prepared to make specific assumptions about the nature of the utility function. The numerical results cited above were obtained for the limiting case in which the substitution effect was assumed zero (corner indifference curves or strict complementarity). As expected, they showed that an increase in r would in steady state lead to a fall in the wealth-income ratio A/Y, and thus to a fall in the saving ratio $S/Y=\rho A/Y$, for any given rate of growth ρ. In terms of the consumption function (10), it was found that a rise in r tended to raise both α and δ. The effect on α was relatively minor but on δ it was proportionately quite large. Specifically, δ appeared to increase linearly with r, or $\delta(r)=\delta^*+\mu r$, with μ roughly unity (and δ^* around .08).

These results of the unpublished paper have since led Modigliani (1973) to conjecture that the effect of r on the LCH consumption function might be approximated by rewriting (10) in the form,

$$\begin{aligned}(11)\qquad C_t &= \alpha YL_t + (\delta^* + \mu r_t)A_t \\ &= \alpha YL_t + \delta^* A_t + \mu(r_t A_t)\end{aligned}$$

with the value of μ depending on the substitution effect between current and future consumption.[22] The value of μ in turn is critical in determining the steady-state response of the saving ratio to changes in r. Indeed, as shown in Modigliani (1973), equation (11) implies the following steady-state relation between the saving ratio, μ, r, and ρ.

---

[22] An expression analogous to (11) has also been derived as a linear approximation by W. H. Somermeyer and R. Bannink, starting from an additive logarithmic utility function except that α is also replaced by α_0+

$$\frac{S}{Y} = \frac{\rho(1 - \alpha)}{\delta^* + \rho + (\mu - \alpha)r} \tag{11'}$$

The calculations of Modigliani-Brumberg reported above suggest that μ might have an upper bound of one in the limiting case of no substitution. Since $\alpha < 1$, it is seen from (11′) that such a value of μ implies that a rise in r reduces S/Y, as expected. But μ would be lower in the presence of substitution. Some simulations reported by James Tobin and Walter Dolde, assuming an iso-elastic additive utility function with an elasticity of 1.5, suggest a value of μ close to zero (see Table 3, simulation 13), which implies that S/Y is an increasing function of r. Another set of calculations reported by Tobin (1967), assuming a logarithmic utility function, implying an elasticity of one and hence greater substitution, shows a stronger positive responsiveness of S/Y to r, suggesting a negative value of μ. Unfortunately, there is no way to establish a priori just how strong the substitution effect might be in reality, and hence what value μ should take—except that it should not exceed unity. Because of a hunch that the substitution effect is unlikely to be strong relative to the income effect, we would rather expect μ positive and not very different from α (which, as can be seen from (11′) would imply that S/Y is roughly independent of r). However, in principle, it could be a good deal lower and even negative.

The generalization of the *LCH* embodied in equation (11) is likely to be especially useful for a developing economy, since the process of development might tend to be accompanied by systematic changes in the rate of return on assets. In addition, it provides a useful link to the Kaldorian form of the consumption function. This can best be seen by noting that r_tA_t may be thought of as the long-run expectation of the flow of profits out of current assets, call it P^p, the capitalization of which at the long-term rate r determines the market value of wealth, i.e., $A_t = P_t^p/r_t$. Hence, (11) can be rewritten in the form

$$C_t = \alpha YL_t + \overset{*}{\delta} A_t + \mu P_t^p \tag{12}$$

Comparing (12) with (4), it is apparent that there are some important similarities between *LCH* and *KH* in that both models assert that C is a linear homogeneous function of labor income and profits, and with different coefficients. The main differences are:

(i) In terms of the arguments in the consumption function: For *LCH*, they are the expected rate of earnings from human effort, closely related to Friedman's return from human capital, and the expected long-run return from current private wealth, in addition to the value of wealth itself. In *KH*, the last variable does not appear and the first two variables supposedly denote current "wages" and "profits"—or, at any rate, no distinction is made between current measured values and long-run expectations.

(ii) In terms of interpretation: For *KH*, the coefficients of YL and P are different because YL and P are received by the members of different castes. The coefficients of these variables can rightly be interpreted as marginal propensities to consume of the members of each caste. In the *LCH*, on the other hand, every household typically earns both kinds of income during at least part of its life cycle, and the coefficient of P^p *cannot* be interpreted

---

$\alpha_1 r_t$. They also show that μ should be negative, but this result reflects the special assumption of a logarithmic utility function. See text below.

as a marginal propensity. It measures, instead, the strength of the substitution effect between current and future consumption. The *LCH* per se has little to say about the value of this coefficient or even about its sign.

Yet the *LCH* permits some inferences about the results that one might expect to find if one were to estimate the coefficient of P^* in the Kaldorian equation (4). Consider first the quantity dC/dP^p which measures the response of C to a change in expected property income. Differentiating (12) totally with respect to P^p, and remembering the relation $P^p - rA = 0$, one obtains

$$\frac{dC}{dP^p} = \mu + \frac{\delta^*}{r} E_{AP} \equiv c_p \tag{13}$$

where E_{AP} is the elasticity of A with respect to P^p. Thus, according to the *LCH* the response of consumption depends on the nature of the change in P^p. If it changes because of a change in A, r constant—which is presumably the most common source of change—then E_{AP} will be one and $dC/dP^p = \mu + \delta^*/r$. But if it changes only because of a change in r, then E_{AP} is zero and $dC/dP^p = \mu$. Thus an increase in profit due to a change in A is sure to increase C and the derivative is likely to exceed α; but, if due to a change in r, it might well be less than α and it could be even negative.

If, as in the present case, the observations are time-series of aggregates for a given country, presumably most of the observed variation in profits must come from variations in A (through saving and dissaving) rather than from variations in r. Hence c_p of (13) must be close to $\mu + \delta^*/r$. Now, as we have seen, the value of δ^* seems to be in the order of .07 and hence δ^*/r is certainly positive and of the order of unity—and could easily be above one. On the other hand, the value of μ is quite uncertain: it is unlikely to exceed unity, but it could be smaller and even negative. Thus c_p could be larger than α and, in fact, it *might well exceed unity*. However, c_p is the coefficient of P^p. On the other hand, in testing the Kaldorian model, it has been customary to use *current* labor income and *current* profit. The difference is not too important in the case of YL because labor income is quite stable; hence, expected income will tend to be roughly proportional to current YL. But the situation is entirely different in the case of P. As was pointed out by Ando and Modigliani (1963), since P tends to fluctuate substantially in response to fluctuations in aggregate demand, P^p must be based on an average experience from the past (as well as other information). Hence, $dC/dP = c_p dP^p/dP$ will be distinctly smaller than c_p, since dP^p/dP is certainly smaller than one and may be close to zero if P exhibits much short-run variation. Thus, independently of the relation of c_p to α, a regression of C on YL and P is most likely to yield a P coefficient much smaller than that of YL, especially since YL will tend to proxy in part for P^p. In the case of the United States, for example, Ando and Modigliani (1963) obtained a coefficient of YL of .93 and a coefficient of P of .07 (totally insignificant). This was true even though A, in contrast to P, contributed very significantly to the explanation of C.

The results of a similar test for Italy have already been reported in connection with our test ~~of the~~ Kaldorian hypothesis and appear in Table 2, equations 2*L* and 2*R*. From those results, one can infer that the coefficient of current profit is only .43, and hence much lower than the coefficient of wages. But according to *LCH*, this low coefficient does not reflect a purportedly low *MPC* out of property income, but rather the fact that current profit P is a poor proxy for wealth and/or expected long-run profit P^p, the truly relevant variables. The supposition receives some indirect support from the fact that the coefficient of P is not only low but also has a

t-ratio which is relatively low, especially when compared with that of $\hat{W}$ (see equation 2) or with that of A in equation 1, Table 3. These results are thus in line with those of Ando-Modigliani (1963) for the United States. But a more telling test, reported in equations $2L$ and $2R$ of Table 3, consists in adding the variable A to the Kaldorian model (or equivalently P to the LCH model); in the linear estimate, the coefficient of P then falls from .42 to .07 and is insignificantly different from zero whereas the A coefficient falls only from .092 to .083 and is still quite significant. Similar results hold for the ratio estimate. These results are consistent with the LCH interpretation that P, in the Kaldorian equations 2 of Table 2, is but a poor proxy for the relevant variables A and P^p.

The validity of this inference is supported by the other results which are reported in Table 2. Indeed, we can now interpret these tests as an endeavor to estimate the coefficient c_p of equation (13), by replacing both A^* and P by an approximation to P^p. As we have already seen in commenting on the results of Table 2, we find that the coefficient of P^p is uniformly larger than that of wages, and that in fact most of the time our estimate is above unity. In particular, when using the more refined approach of equation 5, relying on a Koyck distributed lag on $\hat{P}_{-1}$, our estimate of c_p is as high as 1.5 to 1.9, a value which is perfectly consistent with the LCH framework, as is apparent from (13). This consistency can also be verified by relating the estimate of c_p to the estimate of the coefficient of A^*, δ, in equation 1, Table 3. From equations (10), (11), and (13) it is seen that δ, and the coefficient of P^p, c_p, should be related by

$$(14) \qquad c_p \simeq \frac{\delta^*}{\bar{r}} + \mu \equiv \frac{1}{\bar{r}}(\delta^* + \mu\bar{r}) = \frac{1}{\bar{r}}\delta$$

where $\bar{r}$ is the average value of the return on wealth, $r = P^p/A$ or equivalently the capitalization rate relating the market value of wealth to expected profits, $A = P^p/r$.

Relying on the assumption that r was reasonably stable in the relevant period and that, as in Table 2, P^p can be approximated by a linear combination of $\hat{P}$ and a Koyck lag beginning with $\hat{P}_{-1}$,[23] we can obtain an estimate r, $\hat{r}$, from the regression

$$(15) \qquad A^* = \mu'\hat{P} + \mu''L(\hat{P}_{-1}) + a$$

where $\mu' + \mu'' \simeq 1/\hat{r}$. The results obtained in estimating (15) are shown in equations $3L$ and $3R$, Table 3. The fit is reasonably good considering the rough approximation to A. The estimate of $1/\bar{r}$ implied by $\mu' + \mu''$, 16.5, is not unreasonable (though somewhat on the high side).[24] It is seen from (15) that this estimate of $1/r$ together with the estimate of δ of Table 3 would lead us to expect a value of c_p of around 1.5 (.092x16.6 relying on the linear estimates, .078x16.5 for the ratio estimates), which is quite consistent with the actual estimate.[25]

An attempt was also made to estimate the coefficients of the LCH function in its more general form (12), which includes both A and P^p, in the hope of gaining some

---

[23] We allow for a constant term on the ground that what we measure is not A, but financial wealth A^*, and we hypothesize that the relation of A^* to A can be approximated by

$$A^* = a_0A - a_k = \frac{a_0}{r}P^p - a_1; \quad 0 < a_0 < 1, a_1 > 0$$

since, in the process of development, financial wealth is likely to rise proportionately faster than A (see fn. 21).

[24] Especially since from fn. 23, it is seen that $\mu_1 + \mu_2$ is an estimate of a_0/r and $a_0 < 1$.

[25] Since in the test equations 1 and 2, A^* denotes the value of assets at the end of the *preceding* year, the same is true in (15), and equation 3 of Table 3. Nonetheless, the explanatory variables include *current* profits $\hat{P}$. This was done on the ground that the variable $\hat{P}$ appears in equation 5 of Table 2 and the estimate of c_p is the sum of the coefficient of profits including the current value $\hat{P}$. The very significant contribution of current $\hat{P}$ to the explanation of earlier A^* can be readily accounted for on the hypothesis that $\hat{P}$ is a good proxy for profit expectations for the coming year held at the end of the previous year, which are reflected in A^*.

information on the sign and size of the coefficient of P^p, an estimate of μ in (12) which reflects the strength of the substitution effect.

This attempt runs into serious difficulties because of the unavoidable collinearity of A and P^p, a problem made more serious in the present instance by our use of A^* as a proxy for A. The results are reported in equation 4, Table 3, although we regard them as rather unreliable. They do suggest that the value of μ is positive; however, the point estimate, greater than unity, is above the a priori upper limit, probably as a result of upward biases arising from the fact that our approximation to A is very rough, and hence P^p may partly act as a proxy for A.

On the whole, and subject to the caveat at the beginning of the previous paragraph, the results of equation 4, Table 3 seem to warrant the conclusion that a generalized version of the life cycle model can provide an explanation of consumption in postwar Italy which is substantially superior to that offered by any of the competing hypotheses. They also confirm and throw light on the inference that c_p is well above one. They further suggest that μ of equation (12) is positive at least in the case of Italy, though its numerical value (and therefore, in particular, its relation to α) cannot be reliably estimated with the presently available data.

While these striking results for Italy have not yet been replicated, they receive some support from scattered evidence for other countries. First, Richard Stone, in his 1966 paper, provides us with an explicit estimate of δ^* and μ of equation (12) for the United Kingdom, though his results are based on some rather stringent assumptions which may limit their reliability for our purpose.[26] His estimate of α is .79 and that of μ is positive and in fact only moderately lower, .67; at the same time, the separation of income into labor and property income does not affect the estimate of δ^* which remains .06. It is readily apparent from these estimates that for any reasonable value of the rate of return r, the quantity $.67+.06/r$ will exceed the estimated *MPC* out of labor income of .79, and in fact will exceed unity. These results have been confirmed by his later paper extending the analysis to 1970. In particular, when relying on the alternative measure of consumption excluding durables, the estimates of both α and μ are reduced as expected, but, in addition, the difference between them shrinks further to only about .10 (and with a very small t-ratio).

Finally, for the United States, Warren Weber, following a rather different method of estimation, but allowing explicitly for the effect of the interest rate, has concluded that the partial derivative of C with respect to r is positive, implying again a positive value of μ and, hence again, a value of c_p most probably above unity or at least above α.

One suggestive implication of these conclusions should be to relieve the schizophrenia of many economists and other social scientists who have been torn in the past between advocating a redistribution of income in favor of labor on grounds of equity, and reluctantly accepting a redistribution in favor of profits on the ground that this would increase savings and capital formation and, hence, the potential rate of economic development. Our evidence suggests that a sheer redistribution of a given income from wages to profits would increase savings only in the short-run, but would decrease it in the longer run (since c_p is larger than α). Furthermore, a reduction in the rate of return or rate of profit resulting from a lower productivity of capital or from taxation of property income might also increase saving, although this inference is uncertain since the available evidence does not enable us to conclude with confidence that μ exceeds α in (12), (see equation (11′)).

---

[26] The most sensitive assumptions for our purpose are that: (i) permanent labor income can be approximated by a Koyck lag of the wage and salary component of National Income; (ii) permanent property income P^p is a Koyck distributed lag of the remaining components of income; and (iii) the weights of the distributed lag are the same for the two components.

Interest Rates, Inflation, and Consumer Expenditures

By Warren E. Weber*

The possibility that consumers use different decision rules in making different types of expenditure decisions has been explored in several recent econometric models which use multiequation models to explain consumer expenditures. Two such models are the Brookings model and one particular vintage of the Federal Reserve Board–Massachusetts Institute of Technology (*FRB-MIT*) model.[1] However, these two models do not provide any microeconomic foundations for their regression equations. This neglect leads Daniel Suits and Gordon Sparks to leave interest rates and relative price effects out of the automobile and consumer durables demand equations in the Brookings model. It also leads the *FRB-MIT* model builders to leave interest rates and relative prices out of the determination of the level of consumer expenditures. The only role of interest rates and relative prices is to allocate consumer expenditures among their various components.[2]

The purpose of this paper is to develop a multiequation model of consumer expenditures which uses the individual's intertemporal utility maximization calculus to explain his purchases of durables and nondurables. The approach will extend the basic Fisherine analysis to the case in which the individual can purchase these two types of commodities. For earlier applications, see the consumption function studies of Franco Modigliani and Richard Brumberg, Albert Ando and Modigliani, Milton Friedman, and the author. In addition to human and nonhuman wealth (which includes existing stocks of durables), the consumer demand equations obtained have a nominal interest rate, the relative price of the two commodities, and the anticipated rates of change in the prices of the two commodities as exogenous variables. The construction of the model is such that the level of consumer expenditures may be affected by all of these exogenous variables. Moreover, the nominal interest rate, the relative price of the two commodities, and the anticipated rate of change in the price of durables may affect the allocation of expenditures. These demand functions are then used to test the statistical significance of the interest rate and price variables as determinants of consumer expenditures.[3]

The paper proceeds as follows. Section I contains the derivation of the demand functions for durables and nondurables of a representative consumer. In Section II, specific functional forms for these demand functions are obtained by assuming a specific functional form for the representative consumer's utility function. Section III presents the results of estimating the demand functions derived in Section II using aggregate annual data for the United States for the period 1930–70, omitting 1941–46. Section IV contains a summary and conclusions.

---

* Associate professor of economics, Virginia Polytechnic Institute and State University.

[1] Specifically I refer to the vintage described by Frank de Leeuw and Edwin Gramlich.

[2] This part of the *FRB-MIT* model is described by de Leeuw and Gramlich as follows:

> The sum of the services of durable goods and expenditures on non-durables is the consumption variable that we relate to current and past income, whereas the allocation of the sum among its components depends on relative prices, existing stocks, and other variables. One result of this formulation is a small effect of interest rates on the allocation of total consumption (in our sense) and hence on consumer expenditures on durable goods. [p. 12]

[3] Another study which develops simultaneous expenditure functions is that by W. E. Diewert. The major difference is that the present study explicitly tests the statistical significance of interest rates, relative prices, and anticipated inflation rates as determinants of expenditures.

I. The Representative Consumer's Utility Maximization Problem

Suppose that a representative consumer in the economy begins his economic life at age 0 and lives L years with certainty. He is currently assumed to be at economic age i, so that he has a remaining planning horizon of $L-i-1$ years. He is assumed to receive utility from his consumption of the services of nondurable goods and the services of durable goods in each of the years remaining in his economic lifetime. We assume that the service flows from nondurables and durables are not perfect substitutes in his utility function. Let the services of nondurables and durables which he consumes at age j be denoted by s_j^n and s_j^d, respectively. Under the further assumption that he will not receive any utility from bequests, we can express his utility index as

$$(1)\quad U = U(\overset{n}{s}_i, \ldots, \overset{n}{s}_{L-1}, \overset{d}{s}_i, \ldots, \overset{d}{s}_{L-1})$$

Three further assumptions concerning the representative consumer are now made: 1) He receives an after-tax, nominal labor income of y_j at each age $j=i, \ldots, L-1$. 2) His only alternative to purchasing the services of nondurables or the services of durables in any period is to purchase one-period bonds which promise to pay one dollar at the beginning of the next period. 3) He owns no durables. Under these assumptions his multiperiod wealth constraint is[4]

$$(2)\quad \sum_{j=i}^{L-1}\left(\frac{1}{1+r}\right)^{j-i}(\overset{n}{q}_j\overset{n}{s}_j + \overset{d}{q}_j\overset{d}{s}_j) = b_i + \sum_{j=i}^{L-1}\left(\frac{1}{1+r}\right)^{j-i} y_j$$

where r is the nominal interest rate, b_i is his bond holdings at the beginning of period i, and q_j^n and q_j^d are the prices of nondurable services and durable services which he faces at age j. The multiperiod wealth constraint states that the present value of the individual's consumption of the services of nondurables and durables must equal his total human and nonhuman wealth.

Now define v_i the individual's total of human and nonhuman wealth, and $\underline{q}_i^n$, $\underline{q}_i^d$ the vectors of forward nondurable and durable service prices he faces at age i:

$$(3\text{a})\quad v_i = \sum_{j=i}^{L-1}\left(\frac{1}{1+r}\right)^{j-i} y_j + b_i$$

$$(3\text{b})\quad \underline{\overset{n}{q}}_i = \left\{\overset{n}{q}_i, \left(\frac{1}{1+r}\right)\overset{n}{q}_{i+1}, \ldots, \left(\frac{1}{1+r}\right)^{L-i-1}\overset{n}{q}_{L-1}\right\}$$

$$(3\text{c})\quad \underline{\overset{d}{q}}_i = \left\{\overset{d}{q}_i, \left(\frac{1}{1+r}\right)\overset{d}{q}_{i+1}, \ldots, \left(\frac{1}{1+r}\right)^{L-i-1}\overset{d}{q}_{L-1}\right\}$$

Then, when he maximizes his utility function (1) subject to the wealth constraint (2), his $2(L-i-1)$ demand functions for the services of nondurables and durables will be:

$$(4\text{a})\quad \overset{n}{s}_j = \overset{n}{s}_j(\underline{\overset{n}{q}}_i, \underline{\overset{d}{q}}_i, v_i)\qquad j=i, \ldots, L-i-1$$

$$(4\text{b})\quad \overset{d}{s}_j = \overset{d}{s}_j(\underline{\overset{n}{q}}_i, \underline{\overset{d}{q}}_i, v_i)\qquad j=i, \ldots, L-i-1$$

These demand functions are homogeneous

---

[4] This wealth constraint also contains the implicit assumption that the individual can borrow and lend at the same interest rate in all periods. This assumption is made to simplify the empirical analysis of this paper.

of degree zero in q_i^n, q_i^d, and v_i.

The functions (4a) and (4b) are the representative consumer's demand functions for services of nondurables and durables. They would be sufficient to explain consumer expenditures on durables and nondurables if he were able to rent the services of these two commodities directly. In general, however, this is not the case for nondurables since usually units of the commodity must be purchased in order to obtain the service flow. Further, we will assume that a rental market for the services of durables does not exist and that the only way in which the representative consumer can obtain the services of durables is to purchase units of the durable good and then "rent" the service to himself.[5]

Thus, there are two problems in converting the service demand functions of the representative consumer into the purchase demand functions for units of nondurables and durables. The first is determining the service flows which are obtainable from newly purchased and existing units of the commodity. The second, which arises here only for durables, is determining the nature of the resale market for existing units of the good. Of course, the relationship between the service flows obtainable from newly purchased units of the commodity and existing units of the commodity may have definite implications for the resale market. Thus, the solution of the first problem may have definite implications for the solution of the second problem.

We solve the service flow and rental market problems for nondurables as follows. The service flow from units of nondurables is assumed to be equal to the units of nondurables purchased during the period. Since nondurables in our model are goods which fully depreciate by the end of the period, there is no resale market to consider. Consequently, a demand for the services of nondurables causes an immediate demand to purchase nondurables.

The service flow and rental market problems for durables are handled in the following way. The service flow from a particular stock of durables is assumed to be a constant proportion of the size of this stock. In addition, the service flow from a unit of existing durables *properly depreciated* is assumed to be same as that from a unit of newly purchased durables. For example, a one-year old TV is assumed to yield a service flow which is $(1-\delta)$ times the service flow for a new TV, where $0<\delta<1$ is the proper depreciation rate.[6] Combining these two assumptions means that the flow of durable services is a constant proportion of the stock of durables held in the period, when this stock is measured in units of new durables.

These assumptions concerning service flows from new and existing durables have definite implications for the resale market for existing durables. In the absence of transactions costs in the sale of existing durables, these assumptions imply that existing durables and new durables must, by the law of indifference, sell at the same price per unit of remaining potential service. These assumptions also imply that a demand for the services of durables gives rise to a reservation demand for durables. However, unlike the demand for nondurable services, the demand for durable services will give rise to a purchase demand for durables only if the reservation demand for durables differs from the individual's current holdings of durables.

---

[5] This assumption does not appear unreasonable when it is considered that our representative consumer's durable purchase demand function will be our aggregate demand function. However, it does point out a double-counting problem which would arise if interhousehold rentals of durables were included in the data used in the empirical analysis. This point will be considered later in the paper.

[6] There are, of course, other depreciation assumptions which could be made, such as the "one-horse shay" type mentioned by Richard Parks. An alternative type of assumption would be that the depreciation rate depends upon the usage of the durable. However, we choose the constant, use-independent depreciation rate here for convenience.

Let n_j be the consumer's purchases of nondurables at age j and let d_j be his *holdings* of durables during age j. Then under our assumptions relating the flows of services of nondurables and durables to the stocks of these commodities, we can replace s_j^n by n_j and s_j^d by d_j in the individual's utility function, and his utility function can now be written as

$$(1') \quad U^* = U^*(n_i, \ldots, n_{L-1}, d_i, \ldots, d_{L-1})$$

Further, his intertemporal decision problem becomes the maximization of (1′), subject to the wealth constraint

$$(2') \quad v_i = \sum_{j=i}^{L-1} \left(\frac{1}{1+r}\right)^{j-i} \cdot \left\{ p_j^n n_j + p_j^d [d_j - (1-\delta) d_{j-1}] \right\}$$

where p_j^n and p_j^d are the purchase prices for nondurables and durables, respectively, which the individual faces at age j.

This wealth constraint, like the wealth constraint (2), is derived under the implicit assumption that the representative consumer believes that he will be able to fully transact his demands in all periods. In other words, the representative consumer is assumed not to face any quantity restrictions on his ability to purchase nondurables at the prevailing prices, on his ability to purchase or sell bonds at the prevailing prices, or on his ability to adjust his durable holdings to his desires. In order for the individual to encounter no quantity adjustment difficulties with respect to durables, we require a well-functioning resale market for existing durables and a perfectly elastic supply curve of new durables at the prevailing price.[7]

From the wealth constraint (2′) we find that we must redefine the individual's total human and nonhuman wealth to include the durables which he owns coming into period i. Further, we find that we can now define the vectors of forward service prices in terms of current and future purchase prices. We will assume throughout that the proportion of service flows to units for both nondurables and durables is unity. Thus we can rewrite (3a)–(3c) as[8]

$$(3a') \quad w_i = v_i + (1-\delta) p_i^d d_{i-1}$$

$$(3b') \quad \underline{p}_i^n = \left\{ p_i^n, \left(\frac{1}{1+r}\right) p_{i+1}^n, \ldots, \left(\frac{1}{1+r}\right)^{L-i-1} p_{L-1}^n \right\}$$

$$(3c') \quad \underline{p}_i^d = \left\{ p_i^d - p_{i+1}^d \left(\frac{1-\delta}{1+r}\right), \left(\frac{1}{1+r}\right) \cdot \left[p_{i+1}^d - p_{i+2}^d \left(\frac{1-\delta}{1+r}\right) \right], \ldots, \left(\frac{1}{1+r}\right)^{L-i-1} \cdot \left[p_{L-1}^d - p_L^d \left(\frac{1-\delta}{1+r}\right) \right] \right\}$$

Then, when the individual maximizes his utility function (1′) subject to the wealth constraint (3a′), his $2(L-i-1)$ demand functions are

$$(4a') \quad n_j = n_j(\underline{p}_i^n, \underline{p}_i^d, w_i) \quad j = i, \ldots, L-1$$

---

[7] It may be objected that whereas a well-developed market for the services of some types of durables does exist, a well-developed resale market only exists for automobiles and some types of appliances. Therefore, a more reasonable assumption would be that an upper bound on the decrease in durables holdings between two periods should be the depreciation rate on durables. We ignore this problem because our demand functions for the representative consumer will be our aggregate demand functions and for the time period under consideration we never observe zero purchases of durables.

[8] The redefinition of q_{L-i-1}^d given by (3c′) is not strictly correct. Since the representative consumer will not be alive in period L, the price of services of durables in $L-i-1$ is $q_{L-i-1} = p_{L-i-1}$. However, since we will assume a long-lived consumer, we will ignore this point here and in the empirical analysis.

$$(4b') \quad d_j = d_j(\underline{p}_i^n, \underline{p}_i^d, w_i) \quad j = i, \ldots, L-1$$

These demand functions are homogeneous of degree zero in $\underline{p}_i^n$, $\underline{p}_i^d$, and w_i.

II. The Specific Model

A. *The Explicit Demand Functions*

In the previous section we developed a prototype model of the consumer's lifetime allocation process for nondurables and durables. In this section we transform the implicit demand functions of the prototype model into explicit demand functions suitable for empirical estimation.

One possible approach to this problem would be to assume that (4a′) and (4b′) are either linear or log-linear in their arguments. However, this solution presents the following difficulty. The classical utility maximization calculus implies certain restrictions on the partial derivatives of a set of demand functions. In our case, however, we are not able to observe the entire set of demand functions since the demands for purchases of nondurables and durables in future periods are not observable. Therefore, in the empirical analysis we would not be able to take advantage of the additional information conveyed by these restrictions.

Thus, our approach to the problem will be to assume that the representative consumer has a utility function of a specific functional form. Maximizing this utility function subject to the consumer's intertemporal wealth constraint will yield explicit demand functions for current purchases of nondurables and durables which place some restrictions on the partial derivatives of these two demand functions.[9]

We first assume that the consumer's utility index for nondurable and durable holdings during any age j is a *CES* utility function of the form

$$(5) \quad u(n_j, d_j) = [\alpha n_j^{-\beta_1} + (1-\alpha) d_j^{-\beta_1}]^{-1/\beta_1} \qquad j = i, \ldots, L-1$$

where $0<\alpha<1$ and $-1<\beta_1<\infty$ $(\beta_1 \neq 0)$ are parameters. We then assume that his utility function for nondurable purchases and durable holdings for his entire lifetime is

$$(6) \quad U_i(\cdot) = \kappa \sum_{j=i}^{L-1} (1+\gamma)^{j-i} u(n_j, d_j)^{-\beta_2}$$

where $\gamma > -1$, $-1 < \beta_2 < \infty$ $(\beta_2 \neq 0)$, and κ are parameters. The utility function (6) is a monotonic transformation of Kazuo Sato's two-level *CES* production function.[10] The restrictions on the parameters given above plus the restriction that $\kappa\beta_2 < 0$ assure that (6) is strictly quasi concave with positive marginal utilities of nondurable purchases and durable holdings. In (5) the parameter α indicates the distribution of utility between the two goods in any period. In (6) the parameter γ is the individual's subjective rate of time preference.

The interpretation of the parameters $\sigma_1 = 1/(1+\beta_1)$ and $\sigma_2 = 1/(1+\beta_2)$ is best obtained by following Sato's terminology. He calls σ_1 the "intraclass" elasticity of substitution. It is the elasticity of substitution within a particular class of goods, ignoring any substitutability among classes. Thus, for our model σ_1 can be interpreted as the elasticity of substitution of nondurable and durable services at any age when any intertemporal substitution effects are ignored. Sato calls σ_2 the "interclass" elasticity of substitution. It is the elasticity of substitution among input groups. Thus, σ_2 is the elasticity of substitution between

---

[9] This approach of deriving explicit functional forms using explicit utility functions has been used before. A list of references is given on pp. 591–92 of my earlier consumption function study.

[10] The same kind of utility function is used by Laurits Christensen in his analysis of the effects of the rate of return on saving. The inputs in his utility function are consumption and leisure.

$$(7a) \qquad k_j(\cdot) = \left[\frac{\alpha}{1-\alpha}\rho_j\right]^{-\sigma_1} \qquad j = i, \ldots, L-1$$

$$(7b) \qquad h_j(\cdot) = 1 + \rho_j k_j(\cdot) \qquad j = i, \ldots, L-1$$

$$(7c) \quad g_i(\cdot)^{-1} = h_i(\cdot)^{(\sigma_2-\sigma_1)/(1-\sigma_1)} \sum_{j=i}^{L-1} h_j(\cdot)^{(1-\sigma_2)/(1-\sigma_1)} \left\{\left[\left(\frac{1}{1+r}\right)(1+\gamma)^{1/\beta_2}\right]^{j-i} (p_j^n/p_i^n)\right\}^{1-\sigma_2}$$

where $$\rho_j = \left[p_j^d - p_{j+1}^d\left(\frac{1-\delta}{1+r}\right)\right] \Big/ p_j^n$$

pairs of either $(n_j, n_{j'})$, $(d_j, d_{j'})$, or $(n_j, d_{j'})$ where $j \neq j'$.[11]

We now define three additional variables to aid in the presentation of the explicit demand functions which result from the maximization of (6) subject to the intertemporal wealth constraint (2a′). These new variables are shown in (7a)–(7c). Using this notation, the individual's explicit purchase demand function for nondurables and his reservation demand function for durables in the current period are

$$(8a) \qquad n_i = g_i(\cdot)w_i/p_i^n$$

$$(8b) \qquad d_i = k_i(\cdot)n_i$$

His total dollar expenditures for durable and nondurable purchases are[12]

$$(9) \quad p_i^n n_i + p_i^d d_i = [1 + (p_i^d/p_i^n)k_i(\cdot)]g_i(\cdot)w_i$$

Thus, from (8) and (9) we see that $g_i(\cdot)$ is the individual's marginal propensity to purchase nondurables out of total current wealth, that $k_i(\cdot)$ is his desired ratio of durable holdings to nondurable holdings, and that $[1+(p_i^d/p_i^n)k_i(\cdot)]g_i(\cdot)$ is his marginal propensity to purchase out of current wealth.

B. *Expectations and Unobservable Variables*

A final step remains before the demand functions (8a) and (8b) can be estimated. These demand functions have future purchase prices and future labor income (through human wealth) as exogenous variables. Since these variables are not directly observable, we must relate them to observable variables in order to estimate the demand equations. Specific assumptions concerning the way in which the representative consumer forms his expectations are part of our maintained hypothesis.

We will very simply assume that the representative consumer expects some constant rate of inflation or deflation π^n in the purchase price of nondurables and some constant rate of inflation or deflation π^d in the purchase price of durables. Of course, these expected rates of price change do not need to be the same. Under these assumptions, the future purchase prices of nondurables and durables are related to current (observable) purchase prices according to

---

[11] The relationship between σ_1 and σ_2 and the Allen partial elasticities of substitution is discussed by Sato.

[12] This is not, however, the individual's nominal consumption during age i which is given instead by his total dollar expenditures on *services* of nondurables and durables during the period $(q_i^n n_i + q_i^d d_i)$. The difference between consumption and expenditures arises because the service price of durables is not equal to the purchase price of durables since the individual can purchase durables in order to rent them to himself in more than one period. His consumption of durables in any period is therefore equal to the amount of "rental income" which he pays himself in that period. This rental income does not bear any direct relation to his purchases of durables during that period. As Michael Farrell and Daniel Suits correctly point out, it is consumer expenditures and not consumption which affect employment, production, and income in the economy.

$$\text{(10a)}\quad p_j^n = (1+\pi^n)^{j-i} p_i^n \quad j = i+1, \ldots, L-1$$

$$\text{(10b)}\quad p_j^d = (1+\pi^d)^{j-i} p_i^d \quad j = i+1, \ldots, L-1$$

Further, we assume that the representative consumer forms his expectations concerning future nominal labor income in very much the same way that he forms his expectations concerning future prices. We assume that he expects his nominal future labor income to grow at the constant rate $\xi+\pi$ over the remainder of his economic lifetime. Under this assumption his future nominal labor income is related to his current nominal labor income according to

$$\text{(10c)}\qquad y_j = (1 + \xi + \pi)^{j-i} y_i \qquad j = i + 1, \ldots, L - 1$$

In this formulation ξ reflects expected changes in nominal labor income caused by changes in productivity and π reflects nominal labor income growth caused by expected secular inflation. When π is viewed in this light, it is obvious that this inflation rate need not be the same as the anticipated inflation rates for either nondurable or durable prices.

The assumptions (10a)–(10c), however, do not completely solve our unobservable variables problem, but only serve to reduce the number of unobservable variables in the model since the three expected inflation rates are themselves not observable. We must now consider the problem of how the representative consumer forms his expectations concerning these rates of inflation. One possibility which has been used a great deal in the literature is to assume that the consumer uses an adaptive expectations mechanism to form his expectations. Suppose that we are considering the consumer's expectations concerning the rate of inflation in the price on nondurables. Suraj Gupta has shown that the adaptive expectations framework can be written as

$$\text{(11)}\qquad \hat{\pi}^n = \phi[ln\,(p_i^n) - ln\,(\hat{p}_i^n)]$$

where $\hat{p}_i^n$ is the price of nondurables which the consumer expected to hold at age i. This expectations framework states that if the current price level is above the "normal" price level which the consumer expected to prevail in this period, then he will expect the price level to continue to increase in the future. Gupta goes on to show that (11) can be written as

$$\text{(12)}\qquad \hat{\pi}^n = (1 - \lambda) \sum_{j=0}^{T} \lambda^j \pi_{i-j}^n, \qquad T \leq i$$

where $\lambda = e^{-\phi}$ and π_{i-j}^n is the inflation rate which the individual observed at age $i-j$. Thus, under the adaptive expectations scheme the individual forms his expectation of the rate of inflation which will occur in the future by taking a weighted average of all past inflation rates.

However, Gupta proposes a second expectations scheme, namely,

$$\text{(13)}\qquad \bar{\pi}^n = \phi'[ln\,(\hat{p}_{i+1}^n) - ln\,(p_i^n)]$$

This expectations framework states that if the current price level is above the normal price level which the consumer expects to prevail in the future, then the consumer expects a negative rate of inflation as the price level returns to its normal level.

There is, of course, no a priori way to choose between these two hypotheses. However, Gupta is able to show that

$$\text{(14)}\qquad \bar{\pi}^n = \hat{\pi}^n[\phi'(\phi - 1)/\phi]$$

indicating that these two expectations hypotheses will be negatively related if $0<\phi<1$, the generally expected case.

Therefore, in order to allow for either of these cases to occur we will assume that the consumer forms his expectations concerning the rate of inflation of the price of nondurables according to

$$(15a) \qquad 1 + \pi^n = \theta_1 + \theta_2\hat{\pi}^n$$

This formulation has two advantages. First of all, it allows either (11) or (13) to obtain through the parameter θ_2. If $\theta_2 > 0$, then this formulation argues that the consumer is forming his expectations according to (11). However, if $\theta_2 < 0$, then it argues that the consumer is forming his expectations according to (13). Secondly, it allows us to test whether changes in inflation rates have an effect on consumer expenditures by testing whether or not θ_2 is significantly different from zero.

The constant θ_1 in (15a) is included to allow for the fact that the consumer may have an expectation of a nonzero long-term normal rate of inflation which is not influenced by any changes in past inflation rates. In other words, if the individual has a normal inflation rate which is not affected by current or past inflation rates, then $\theta_2 = 0$. However, in this case $(1+\pi^n)$ does not necessarily have to equal unity. Including θ_1 in the analysis takes this eventuality into account. We expect $\theta_1 > 0$, since it is improbable that the consumer would have a long-run expectation of a deflation rate of 100 percent per year.

We will use exactly the same procedure to relate the consumer's expectations concerning the rate of inflation in the price of durables and the rate of inflation which he sees as relevant to his nominal labor income growth. Consequently, we include the assumptions

$$(15b) \qquad 1 + \pi^d = \theta_3 + \theta_4\hat{\pi}^d$$

$$(15c) \qquad 1 + \xi + \pi = \theta_5 + \theta_6\hat{\pi}$$

as a part of the maintained hypothesis of our model. We expect θ_3 and θ_5 to be strictly positive.

Next, we consider the nominal interest rate to be used in the empirical analysis. The representative consumer may have long-run expectations concerning nominal interest rates which should be included in his demand functions. However, these expectations may or may not be sensitive to changes in current market interest rates, and they may not be solely related to the current level of an arbitrary market interest rate. In addition, they may be formed either adaptively in a manner similar to (11) or according to Gupta's alternative expectations scheme in a manner similar to (13). Therefore, to take account of these possibilities we redefine the nominal interest rate used in empirical analysis along the lines used for the inflation rates. Consequently, we include the assumption

$$(15d) \qquad 1 + r = \theta_7 + \theta_8\hat{r}$$

$$\text{where } \hat{r} = \left[(1-\lambda')\sum_{j=0}^{T} (\lambda')^j r^m_{i-j}\right], \qquad T \leq i$$

and r^m_{i-j} is a particular market interest rate which the individual observed at age $i-j$, as a part of our maintained hypothesis. This formulation affords the same advantages with respect to the nominal interest rate as assumptions (15a)–(15c) do with respect to the inflation rates. The constant θ_7 allows the consumer to have a nonzero long-run expected interest rate even if his expectation is not affected by changes in current market interest rates. The constant θ_8 allows us both to test whether interest rate expectations are influenced by changes in current market interest rates and to discriminate between the competing expectations hypotheses (11) and (13).

There is one final data problem which we must consider. The data available on the prices of nondurables and durables are price index data. These data cannot be used directly to measure the relative price of nondurables and durables since the ratio of the price indices of the two commodities is not necessarily equal to the relative price of the two commodities. Consequently, we assume that relative prices in the model are related to the ratio of the price indices according to

$$\frac{p_i^d}{p_i^n} = \theta_9 + \theta_{10} P^I \tag{15e}$$

where P^I is the ratio of the price index of durables to the price index of nondurables. The formulation (15e) allows the effects of relative price changes on the consumer's demands for nondurables and durables to be statistically tested through θ_{10}.

The problem of not being able to obtain data on relative prices also affects the model in a second respect. If we measure units of nondurables and durables purchased by dividing dollar expenditures by the price indices for the two commodities, we run into the problem that the constant dollar expenditures thus obtained are not necessarily in correct units. To circumvent this problem we will assume that the price index for nondurables is the "true price" of nondurables and then express the demand for durables in *units of nondurables* by dividing dollar demands for durables by the price index for nondurables.

If we substitute (10) and (15) into (8), we would obtain the individual's demand functions for nondurables and durables in terms of only observable variables. However, in the resultant demand functions we would encounter an "identification" problem. This problem is that in these demand functions the effects of one or more of the parameters in the model cannot be distinguished empirically. Consequently, it is necessary to reparameterize the model as follows. Define the vector of parameters $\underline{z} = (z_1, \ldots, z_{10})$ to be:

$$\begin{aligned}
z_1 &= \theta_7/[\theta_3(1-\delta)] \\
z_2 &= \theta_8/[\theta_3(1-\delta)] \\
z_3 &= \theta_4/\theta_3 \\
z_4 &= \theta_9\left(\frac{\alpha}{1-\alpha}\right)^{-\sigma_1/(1-\sigma_1)} \\
z_5 &= \theta_{10}\left(\frac{\alpha}{1-\alpha}\right)^{-\sigma_1/(1-\sigma_1)} \\
z_6 &= \theta_1/\theta_3 \\
z_7 &= \theta_2/\theta_3 \\
z_8 &= \theta_7/[\theta_1(1+\gamma)^{1/\beta_2}] \\
z_9 &= \theta_6/\theta_5 \\
z_{10} &= \theta_7/\theta_5
\end{aligned} \tag{16}$$

In terms of this new notation, the explicit demand functions for nondurables and durables of the individual in terms of only observable variables are

$$n_i = g_i^e(\cdot) w_i^e / p_i^n \tag{8a$'$}$$

$$d_i^* = k_i^e(\cdot) n_i \tag{8b$'$}$$

where $d_i^* = p_i^d d_i / p_i^n$ and $g_i^e(\cdot)$, $k_i^e(\cdot)$, and w_i^e denote $g_i(\cdot)$, $p_i^d k_i(\cdot)/p_i^n$, and w_i after substituting (15) and (16).

The demand functions (8a′) and (8b′) will form the basis of our empirical analysis.[18] These demand functions have the property that both the level and composition of the consumer's expenditures may be affected by changes in nominal interest rates, by changes in the rate of inflation in the price of durables, and by changes in the current relative prices of durables and

[18] For the most part, the demand for purchase of consumer durables has been estimated using a stock adjustment model similar to that of R. Stone and D. A. Rowe. See, for example, the studies by Michael Hamburger, David Huang, and De-Min Wu. This model states that consumers purchase durables in order to reduce the gap between their current holdings of durables and their desired stock of durables by some percentage. Some of the reasons advanced for incomplete adjustment are habit persistence and financial considerations. Our formulation of the model in terms of the intertemporal utility maximization problem of the individual has taken habit persistence and financial considerations into account and eliminated the need to use the stock adjustment framework. Thus, the individual's demand to purchase durables in our model is the difference between his reservation demand given by (8b′) and his current holdings of durables.

nondurables. The level of his expenditures, but not their composition, may be affected by changes in the rate of inflation of the price of nondurables.

III. An Empirical Test of the Model

The model of consumer demand for nondurables and durables is estimated using annual aggregate data for the United States for the period 1930–70, omitting 1941–46, for a total of 35 observations. The observation period ends in 1970, the last year for which wealth data were available. The aggregate demand for purchase of nondurables and aggregate reservation demand for durables equations which are used as the basis of the empirical estimation are obtained by assuming that (8a′) and (8b′) are the aggregate demand functions when the appropriate planning horizon is assumed.[14] This aggregation assumption, of course, assumes that there are no distribution effects and no demographic effects which would affect aggregate demand. The planning horizon which is used in the analysis is 30 years, which is approximately the life expectancy of an individual whose age is equal to the median age of household heads over the observation period.

Purchases of nondurables are defined to be consumer purchases of nondurables and services. The reservation demand for durables is the sum of current purchases of durables plus beginning of period durable holdings.[15] The beginning of period household wealth variable is the sum of their holdings of land, residential structures, consumer durables, and net financial assets plus the after-tax nonlabor income of both proprietors and nonproprietors. The latter is included to take account of the interest earned on the beginning of period wealth, which is paid during the current period. After-tax labor income is the sum of the after-tax labor income of proprietors and nonproprietors.

Price indices for nondurables and durables are used in the calculation of the relative price variable and the inflation rates of nondurables prices and durables prices. The inflation rate used in the calculation of expected labor income growth is based upon the *GNP* deflator. Two market interest rates are used in the empirical analysis. They are the Moody's Baa corporate bond yield and the Durand's basic yield on corporate bonds with five years to maturity.[16]

The series for the expected inflation rates $\hat{\pi}^n$, $\hat{\pi}^d$, and $\hat{\pi}$ and the expected interest rate series $\hat{r}$ were all calculated from (12) according to

$$(17) \qquad x_t^e = (1-\lambda)x_t + \lambda x_{t-1}^e \quad t = 1930\text{–}70$$

where x_t and x_t^e are the actual and expected inflation or interest rate series in period t, respectively. For any given x_t series and initial value x_0^e for x_{1929}^e, the choice of λ will determine a unique series for x_t^e. All of the expected inflation and interest rate series used in this study were constructed under the assumption that $x_0^e = x_{1930}$, the actual

---

[14] An alternative aggregation procedure would be to sum the demand functions (8a′) and (8b′) over the various age groups in the economy. However, estimating the resulting aggregate demand functions would require data on nonhuman wealth and labor income by age group. Such data are not available.

[15] Consumer rentals of the services of durables from the business sector are included in the purchases of services. However, the amounts of these rentals as measured by the sum of "Laundering in Establishments," "Taxicabs," and one-third of "Automobile Repair, Greasing, Washing, Parking, Storage and Rental" (Table 2.5, *The National Income and Product Accounts of the United States, 1929–1965*) are both a small and decreasing share of total expenditures on services and are small relative to purchases of durables. Therefore, the inclusion of these rentals in our data on nondurable purchases should not affect our empirical results. Further, purchases of durables for the purpose of renting them to others should be included in the national income statistics as purchases of producer durables. Thus, the potential double-counting problem mentioned in fn. 5 does not arise with these data.

[16] A more complete discussion of the sources of the data and the construction of the data will be given on request.

TABLE 1—MAXIMUM LIKELIHOOD ESTIMATES OF (8a′) AND (8b′)
$\lambda=0.50$

	Interest Rate Series			
Parameter	Durand's Basic Yield		Moody's Baa	
σ_1	0.801	(0.987)	0.716	(0.836)

inflation rate or interest rate which prevailed in 1930.[17] The x_t^e series used in the study were also generated for the entire time period 1930–70 to avoid any discontinuities due to the omission of the 1941–46 observations in the empirical analysis. Expected inflation rate and interest rate series generated using several different values of λ were tried in the empirical analysis to determine which value of λ yielded the best fit.

Maximum likelihood estimates of the model (8a′) and (8b′) are presented in Table 1 for both nominal interest rate series.[18] All of the expected interest rate and inflation series used in the estimation were calculated with $\lambda = 0.5$. Other values of λ were tried in other estimations, but the resultant sums of squared residuals were larger than that obtained using the value of 0.5 for λ. The numbers in parentheses to the right of the parameter estimates are approximate upper and lower bounds for 99 percent likelihood ratio confidence intervals on the estimates.[19]

---

[17] Of course, the choice of the initial value of x_0^e is arbitrary and does affect the actual expected series generated. M. Feldstein and G. Chamberlain encounter the same problem and assume that $x_0^e=0$. They, however, have 24 periods of experience preceding the first observation in their sample. I chose my initial condition as described above because I did not have the good fortune of Feldstein and Chamberlain. The reader is referred to their discussion of the general estimation problems involved in using this approach and the references contained therein.

[18] Maximum likelihood estimates of the parameters of the model were obtained as follows. Let $\underline{\epsilon}_t=(e_{1t}, e_{2t})'$ be the vector of error terms in period t and add e_{1t} and e_{2t} to (8a′) and (8b′), respectively. Assume that the $\underline{\epsilon}_t$ are identically and independently distributed bivariate normal random variables with mean vector $\underline{0}$ and covariance matrix $\underline{\Omega}$. Then under this assumption the maximum likelihood estimates of the parameters are obtained by minimizing: (over)

The results indicate that the demand functions fit the data quite well. For the nondurables demand function (8a′), the mean squared errors are 28.1 and 22.4 for the Durand's basic yield and the Moody's Baa rate, respectively. For the durable holdings equation (8b′), the corresponding mean squared errors are 117 and 130. These are quite low when compared to the deviation of the dependent variables about their means. These comparisons are given in the last two rows of the table. These results show that the fit with the nondurable expenditure equation is better than that with the durable holdings equation. Further, the results in the row labelled $T^{-1}\Sigma e_{1t}e_{2t}$ indicate that on the average the errors in the expenditure equations are such that if the regression overpredicts nondurable purchases it will underpredict durable holdings and vice versa.

The results in Table 1 indicate that both the intraclass and interclass elasticities of substitution (σ_1 and σ_2, respectively) are less than unity and the confidence intervals on the estimates indicate that we can reject the null hypotheses that they are equal to zero or one at the 0.01 level of significance. The results on σ_1 indicate that for the consumer sector durable holdings and nondurable purchases in any time period are poor substitutes when intertemporal substitution effects are ignored. The results on σ_2 indicate that for the consumer sector nondurables are poor intertemporal substitutes, durable holdings are poor intertemporal substitutes, and durable holdings in one period are poor substitutes for nondurable purchases in another period.

Because of the sign restrictions on α, δ, θ_3, and θ_5, we know from (16) that the signs of θ_2, θ_4, θ_6, and θ_8 will be the same as the signs of z_7, z_3, z_9, and z_2, respectively. Thus, the results in Table 1 indicate that θ_2, θ_4, and θ_6 are all positive and that θ_8 is negative. The results on θ_2, θ_4, and θ_6 imply that the consumer sector forms its expectations concerning inflation rates according to the adaptive expectations framework (11). The result on θ_8 implies that the consumer sector has an expectation of a long-run normal nominal interest rate, and that if the current nominal interest rate rises above this level, consumers expect interest rates to fall in the future.

These results appear contradictory because increases in the rate of inflation should, in the long run, cause increases in the nominal rate of interest if the real rate of interest remains unchanged. However, the confidence intervals on the parameters z_3, z_7, and z_9 include zero which indicates that we cannot reject at the 0.01 significance level the null hypothesis that con-

---

$$|\Omega| = \left(\sum_{t=1}^{T} e_{1t}^2\right)\left(\sum_{t=1}^{T} e_{2t}^2\right) - \left(\sum_{t=1}^{T} e_{1t}e_{2t}\right)^2$$

where e_{jt} is the residual of equation j in time period t, and T is the number of observations. See E. Malinvaud, pp. 568–70.

[19] The use of likelihood ratio confidence intervals is not standard in the literature. However, a Monte Carlo study by Robert Blattberg, Timothy McGuire, and the author found that the estimated small sample power functions for the likelihood ratio test always tend to unity. Power functions for hypothesis tests based upon estimated variances using the inverse of the information matrix or the inverse of the matrix of second partials of the sum of squared residuals did not. These results suggest that confidence intervals based upon the matrix inverses may be too large in some instances. Likelihood ratio confidence intervals also need not be symmetric as must confidence intervals based upon matrix inverses. Heuristically, there seems to be no justification for restricting confidence intervals to be symmetric in non-linear models. A more extensive treatment of the likelihood function and shortest average confidence intervals is given in S. Wilks.

sumers have constant, long-run expectations concerning inflation rates which are unaffected by changes in current inflation rates. If this is the case, then there is no contradiction at all. This type of expectation concerning inflation rates is consistent with the type of expectations behavior found concerning nominal interest rates.[20]

The results of the empirical investigation to determine whether changes in nominal interest rates, relative purchase prices, and inflation rates affect consumer expenditures are presented in Table 2.[21] Likelihood ratio test statistics are given for various null hypotheses concerning the statistical significance of these variables as determinants of consumer expenditures. These hypothesis tests are suggested by the following results of the theoretical discussion of the model: nominal interest rates will be a determinant of expenditures only if $z_2 \neq 0$. Relative prices will be a determinant of expenditures only if $z_5 \neq 0$. The rates of inflation of nondurables and durables will be determinants of expenditures only if $z_7 \neq 0$ and $z_3 \neq 0$, respectively. The *GNP* deflator will affect expenditures only if $z_9 \neq 0$.

In the first row of Table 2, we test the null hypothesis that the model explains consumer expenditures as well leaving out interest rate, relative price, and inflation rate effects as it does including them. The very high value of the test statistics under this hypothesis indicates that we can reject this null hypothesis at better than the 0.001 level of significance for both interest rate series.

TABLE 2—LIKELIHOOD RATIO STATISTICS FOR TESTS OF SIGNIFICANCE OF NOMINAL INTEREST RATES, RELATIVE PRICES, AND INFLATION RATES

Null Hypothesis	Durand's Basic Yield	Moody's Baa
$z_2 = z_3 = z_5 = z_7 = z_9 = 0$ $(\hat{r}; P^I; \hat{\pi}^d; \hat{\pi}^n; \hat{\pi})$	38.0[a]	43.1[a]
$z_2 = 0$ $(\hat{r})$	6.52[b]	11.3[a]
$z_5 = 0$ (P^I)	24.5[a]	25.5[a]
$z_3 = 0$ $(\hat{\pi}^d)$	1.15	2.81[c]
$z_7 = 0$ $(\hat{\pi}^n)$	3.54[c]	1.78
$z_9 = 0$ $(\hat{\pi})$	0.593	0.094
$z_3 = z_7 = 0$ $(\hat{\pi}^d; \hat{\pi}^n)$	4.10	3.64

[a] Significant at the 0.001 level.
[b] Significant at the 0.025 level.
[c] Significant at the 0.1 level.

In the second row of the table we test the null hypothesis that nominal interest rates are not a statistically significant determinant of expenditures. We find that we can reject this null hypothesis at the 0.001 level when the interest rate series in the empirical analysis is Moody's Baa corporate bond yield and that we can reject this hypothesis at the 0.025 level when the interest rate series is the Durand's basic yield. The null hypothesis that relative prices are not a statistically significant determinant of consumer expenditures is tested in row 3 of the table. For both interest rate series this null hypothesis is rejected at better than the 0.001 level.

The null hypothesis that the inflation rates of nondurable prices, durable prices, and the *GNP* deflator are not determinants of consumer expenditures are tested in rows 4, 5, and 6 of Table 2, respectively. None of these hypotheses can be rejected at even the 0.05 level of significance. Because there was one case in which either the rate of inflation of durable prices or the rate of inflation of nondurable prices was significant at the 0.1 level, we decided to test the further null hypothesis that the inflation rates of durable prices and nondurable prices are simultaneously not determinants of expenditures. The result of this hypothesis test is given in the last row of the table and we find that we cannot reject this null hypothesis at even the 0.1 level of significance.

---

[20] There is a second possible explanation for these results. Robert Lucas and Leonard Rapping state that "... there is little evidence that nominal interest rates adjust to expected inflation with sufficient speed to maintain a constant real rate" (p. 276n). If this is the case, then consumers may not have had enough experience with increases in inflation rates increasing nominal interest rates in the period covered by our observations for this relationship to be part of their expectations structure. The reader is referred to the references in Lucas and Rapping to empirical studies yielding the evidence.

[21] Throughout this study we have referred to (8b′) as a demand for durable holdings equation. However, if the stock of durables held coming into the period is constant, then an increase in the demand to hold durables must give rise to a demand to purchase durables. Hence, our use of this equation to discuss expenditure changes.

Thus, the overall results of the hypothesis tests concerning the significance of nominal interest rates, relative prices, and inflation rates as determinants of consumer expenditures indicate that changes in nominal interest rates and relative prices do influence consumer expenditures, but that changes in inflation rates do not.

The effects of changes in relative prices, interest rates, and inflation rates on the model are given in Table 3. Here it is found that an increase in the relative price of durables P^I has the expected effect of increasing the marginal propensity to purchase nondurables and to lower the ratio of desired durable holdings to nondurable purchases. The results of these effects are seen to be that consumers increase the expenditures on nondurables and decrease their durable purchases. However, the overall effect is to increase total expenditures.

The results in Table 3 indicate that an increase in the weighted average of current and past nominal interest rates ($\hat{r}$) has the effect of decreasing the marginal propensity to purchase nondurables and slightly increasing the desired ratio of durable holdings to nondurable purchases. Further, the results indicate that this increase in $\hat{r}$ increases consumers' expected total human and nonhuman wealth (w^e). The overall effect of an increase in $\hat{r}$ is to increase consumer expenditures on durables and nondurables.

TABLE 3—RELATIVE PRICE, NOMINAL INTEREST RATE, AND INFLATION RATE EFFECTS (BOTH INTEREST RATE SERIES)

	Δg^e	Δk^e	Δw^e	Δn	Δd	$\Delta(n+d)$
ΔP^I	+	−	0	+	−	+
$\Delta \hat{r}$	−	+[a]	+	+	+	+
$\Delta \hat{\pi}^d$	−	+	0	−	−	−
$\Delta \hat{\pi}^n$	−	0	0	−	−	−
$\Delta \hat{\pi}$	0	0	+	+	+	+

[a] Positive, but very small.

In order to explain these results it is necessary to recall the type of expectations behavior concerning interest rates indicated by the parameter estimates in Table 1. The results indicated that consumers view an increase in the weighted average of current and past nominal interest rates as indicating that nominal interest rates will be lower in the future. These expected lower interest rates increase the present value of the stream of future labor income and cause consumers to increase their expenditures due to the higher value of their human wealth.

An alternative explanation of this interest rate effect is that a high current nominal interest rate which raises $\hat{r}$ indicates that in the current period consumers can earn a higher than their expected normal rate of return on bonds. Consequently, they can achieve the same real income in the future with a smaller amount of bond purchases. They respond to this opportunity by increasing the expenditures on nondurables and durables in the current period.

The results of the hypothesis tests in Table 2 indicate that changes in current inflation rates are not statistically significant determinants of expenditures. However, we also present the signs of the effects of changes in these rates indicated by the parameter estimates given in Table 1 as a check on our empirical results. Since the results indicate that consumers form expectations concerning the rate of inflation adaptively, we would expect signs of changes in $\hat{\pi}^n$ and $\hat{\pi}^d$ on consumer expenditures to be the opposite of those of $\hat{r}$. We would also expect that an increase in $\hat{\pi}^d$ would cause consumers to increase their desired ratio of durable holdings to nondurable purchases because it lowers the price of durables *services* relative to nondurables *services*. Further, increases in $\hat{\pi}$ indicate that consumers expect future secular increases in their nominal labor income which we would expect to cause them to increase their current period expenditures. The results in Table 3 are consistent with all of these a priori expectations.

IV. Summary and Conclusions

In this paper we constructed an intertemporal utility maximizing model of consumer behavior for the case in which consumers can purchase both durable and nondurable goods. From this model we were able to obtain a reservation demand function for current durable holdings and a demand function for current nondurable purchases which included total human and nonhuman wealth, nominal interest rates, relative prices, and inflation rates as independent variables. Further, the model was constructed in such a way that it was possible to test whether nominal interest rates, relative prices, and inflation rates were statistically significant determinants of consumer expenditures.

An empirical estimation of the model over the period 1930–70, omitting 1941–46, and using aggregate data for the United States indicated that nominal interest rates and relative prices were statistically significant determinants of consumer expenditures. However, the empirical results also indicated that the null hypothesis that changes in inflation rates do not affect expenditures cannot be rejected.

The results of the empirical estimation were also used to determine the direction of nominal interest rate and relative price changes upon expenditures. Here it was found that an increase in the weighted average of current and past nominal interest rates would increase consumer expenditures on both nondurables and durables. This finding is in accord with that of my earlier study of consumption. It was also found that an increase in the relative price of durables would cause consumers to decrease their expenditures on durables and to increase their expenditures on nondurables. The overall effect of the increase would be to increase total expenditure.

Exchange Rates and Fiscal Policy in a Popular Model of International Trade

By RUDIGER DORNBUSCH*

This paper develops a reinterpretation of the devaluation analysis in a popular model of international trade developed by Charles Bickerdike, Joan Robinson, and Lloyd Metzler. It has come to be known as the "elasticity approach."[1] That model, developed in terms of independent markets for imports and exports, has been criticized for its apparent lack of general equilibrium properties. The assumptions underlying the model have remained by and large implicit and vary across users, and the integration of this analysis with the "absorption approach" and macroeconomics has never been demonstrated. All this is very much recognized and indeed application of the model is consistently accompanied by appropriate "partial equilibrium," "impact effect," or "upper bound" caveats. These shortcomings notwithstanding, the model continues to enjoy substantial popularity in policy discussions and interpretations of current events, in empirical work, and in recent textbooks in the field of international economics.[2]

The *BRM* model is likely to remain the preferred tool in the analysis of trade balance issues—along with the foreign trade multiplier model. It is therefore interesting and useful to enquire into its formal general equilibrium implications. This paper is concerned with one such interpretation involving a nontraded goods sector and a well-defined government policy that makes the analysis consistent with the absorption approach. While it may well be possible to generate alternative interpretations, the present analysis would seem to have the advantage of simplicity while at the same time pointing out the essential properties that would have to be satisfied by alternative treatments.

In Section I a brief review of the *BRM* approach is offered. In Section II that approach is interpreted in terms of a simple model with nontraded goods and constant terms of trade. The implicit assumptions of the *BRM* model are brought to the foreground by an explicit consideration of the market for home goods, the equilibrium conditions, and the role of the relative price of nontraded goods.[3] Following that analysis, Section III considers the subsidiary issues that are raised by variable terms of trade. The notion of "total" elasticities is given an interpretation in Section IV where we return to the composite traded good model to explore alternative assumptions about absorption policies.

I. The Bickerdike-Robinson-Metzler Model

The *BRM* model discusses the effects of exchange rate changes in terms of separate markets for imports and exports. In each market, demand and supply depend only

---

* Associate professor, Massachusetts Institute of Technology. I am indebted to Ronald Jones and Michael Mussa for helpful discussions.

[1] In this analysis it will be referred to as the *BRM* model.

[2] See, for example, the articles by William Branson and Stephen Magee (1973, 1975); and the textbooks by Robert Heller, Mordechai Kreinin, and Robert Stern.

[3] Throughout this paper the terms home goods and nontraded goods are used interchangeably. This use differs from the Keynesian tradition where home goods are identified with exportables because the constancy of absolute and hence relative prices of domestically produced goods allows them to be aggregated.

on the *nominal* price in terms of the importing or exporting country's currency, and cross-price effects between markets do not exist. The model is defined in equations (1) to (5):

$$M(P_m) = X^*(P_m^*) \tag{1}$$

$$X(P_x) = M^*(P_x^*) \tag{2}$$

$$B = P_x X - P_m M \tag{3}$$

$$P_m = P_m^* e \tag{4}$$

$$P_x = P_x^* e \tag{5}$$

where[4]

M, X = domestic imports and exports
M^*, X^* = foreign imports and exports
P_m, P_x = the domestic currency prices of (domestic) imports and exports
P_m^*, P_x^* = the foreign currency prices of imports and exports
e = the domestic currency price of foreign exchange

Equation (1) is the equilibrium condition in the market for the home country's imports, and equation (2) is the equilibrium condition for the export market. Equation (3) defines the home country's trade balance surplus measured in terms of domestic currency. Equations (4) and (5) relate the domestic and foreign currency prices of goods via the exchange rate.

The initial equilibrium is shown in Figure 1 at the intersection of the solid demand and supply schedules drawn for an exchange rate e^0. At that initial equilibrium the value of imports $P_m^0 M^0$ is equal to the value of exports $P_x^0 X^0$ so that the trade balance is in equilibrium.

Consider now a devaluation by the home country. The home demand for imports and supply of exports, drawn against their domestic currency prices, will remain unaffected. The foreign supply and demand schedules, however, will shift. In order to maintain the foreign currency price of goods, by (4) and (5) the domestic currency price would have to rise in the same proportion as the exchange rate. It follows that both the foreign supply and demand schedule shift upward in the same proportion as the rate of devaluation. The new equilibrium obtains where both markets clear. The domestic price of imports and exports increases to P_m^1 and P_x^1, respectively; imports decline to M^1 and exports expand to X^1.

The effect of a devaluation on the trade balance in this model is ambiguous. While the value of exports increases, the value of imports may rise or fall depending on the elasticity of demand. A sufficient condition for trade balance improvement is provided by the familiar *BRM* condition.[5]

The disturbing features of this model arise primarily from its apparent disagreement with general equilibrium analysis. The particular questions that arise are the following:

> Why should the behavioral equations depend on a single money price, rather than on relative prices and real income or real expenditure.
>
> The budget constraint would imply that not all markets can be independent so that there must either be additional markets not accounted for explicitly in the model or else the model violates the budget constraint.
>
> It is well known from the absorption approach that a trade balance surplus corresponds to an excess of income over expenditure; to the extent that a devaluation in this model generates a trade balance surplus it must at the same time lower expenditure relative to income in a manner that is in no way explained in equations (1)–(5).

---

[4] All starred variables or quantities denote the foreign country.

[5] See equation (20′) below.

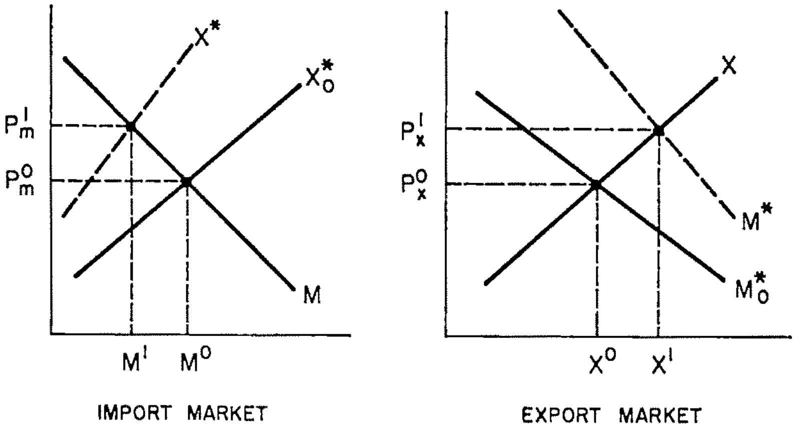

Figure 1

None of these questions is particularly novel; indeed it is well understood by now that there are some things in the background and that some of these things are being held constant. Since these background stories are essential to the operation of the model, it is important to establish what exactly is implicitly assumed.

One interpretation takes a monetary view of the problem and assumes that there is another good in each country, money, and that the nominal quantity of money is fixed. The real effects of a devaluation derive in this formulation from the effect on expenditure of the reduction in the real value of money attendant upon a devaluation.[6]

An alternative and more accepted interpretation assumes that there is another commodity in each country, a nontraded good or home good, and that there is an active policy of maintaining constant some nominal quantity. Among the nominal quantities to be held constant, the following have been alternatively suggested: money income; money expenditure; wages; the price level; or the prices of a particular class of commodities.[7] It is this latter interpretation that we want to develop by an explicit consideration of the market for nontraded goods. That analysis will show that the formulation in Figure 1 can be interpreted to assume the following:[8]

> A nominal price of home goods that is maintained constant in each country by fiscal policy;[9]
>
> A unit marginal propensity to spend on nontraded goods;[10]

---

[6] For such an interpretation see Murray Kemp (1969), Takashi Negishi, and the author (1973).

[7] See in particular the articles by Charles Kennedy, Sidney Alexander, Fritz Machlup, June Flanders, Gottfried Haberler, Ronald Jones (1961), and the book by James Meade.

[8] Kemp (1962, 1969) provides an identical list.

[9] The discussion in this paper is developed in terms of fiscal policy although what is essentially required is a policy that will control absorption so that alternatively the argument could be developed in terms of monetary policy. In the present context we assume (implicitly) that a Meade-type "neutral monetary policy" is pursued so as to maintain constant the rate of interest and thereby allow us to disregard the interrelationship between goods and asset markets. For a further discussion, see the author (1974).

[10] An alternative view that interprets the behavioral equations as reduced forms and thereby allows for positive marginal propensities to spend on traded goods is developed in Section IV. The assumption of a zero marginal propensity to spend on traded goods is obviously quite extraordinary and the reader is reminded that I am not constructing the preferred model of the trade balance, but rather seek to explain the *BRM* model.

Zero cross-price effects (substitution effects) between traded goods.

This set of assumptions, as will be shown below, ensures that there is no feedback effect from the "background" and that fiscal policy eliminates any market disequilibrium that arises in the nontraded goods market. It explains at the same time that the trade balance effects of a devaluation are due to the fiscal policy a devaluation brings into operation.

II. A Simple Model with Nontraded Goods

In this section a simple model is developed with nontraded goods. It is assumed that the relative price of traded goods is constant so that there is only one composite traded good in the world and one nontraded good in each country. The assumption of one composite traded good is a convenience that allows us to disregard terms of trade issues and instead focus consideration on the relative price of traded goods in terms of home goods and on absorption.[11]

Figure 2 shows the Salter diagram with the full employment transformation curve VV between traded goods production Q_I and nontraded goods Q_N, as well as indifference curves. The shape of the indifference curves reflects the assumption that the marginal propensity to spend on home goods is unity so that the indifference curves are laterally parallel. Full equilibrium obtains at point E where income equals expenditure and where the demand and supply of traded and nontraded goods are respectively equal so that both the home-goods market clears and the trade balance is in equilibrium.

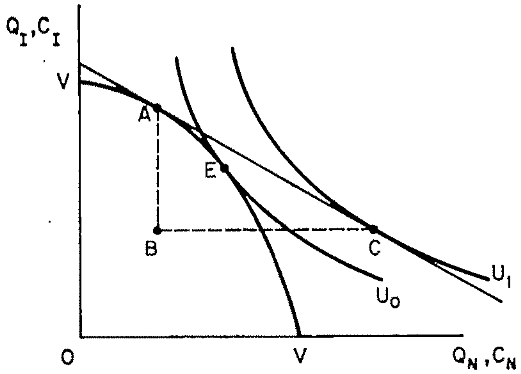

FIGURE 2

An increase in the relative price of traded goods moves the production equilibrium from E to A while moving consumption from E to C; productive resources move into the traded goods industry while consumers substitute from traded to nontraded goods. At that higher relative price there is an excess demand for nontraded goods equal to BC, and an excess supply of traded goods equal to AB. We note, too, that the trade balance surplus AB, measured in terms of nontraded goods, is equal to the excess demand for nontraded goods. The latter equality is an implication of the assumption that income equals expenditure.

Consider now the operation of fiscal policy. We will assume that fiscal policy is used to maintain fixed the *nominal* price of home goods. This implies that any changes in the nominal prices of traded goods, as brought about by an exchange rate change, constitute changes in the relative prices of traded goods in terms of home goods. It implies, too, that the government has to levy income taxes whenever there is an excess demand for home goods; the increase in income taxes reduces private expenditure thereby eliminating the excess demand and preventing the price of home goods from rising. Conversely, when there is an excess supply of nontraded goods so that their price would tend to decline, income transfers are required so as to raise private expenditure and eliminate the excess supply.

The assumption that the marginal propensity to spend on home goods is equal to one becomes important now, since it implies that the tax collection in response to an excess demand has to be identically equal to the excess demand. This can be seen from Figure 2 by noting that in order to eliminate the excess demand for nontraded goods BC, consumption has to move to point B, which requires that the budget constraint facing consumers pass through that point, which in turn implies that disposable income declines by the distance BC due to the income taxes.

---

[11] The model developed here is a two-country version of W. E. G. Salter's "dependent economy" model.

A further implication of the unit marginal propensity to spend on home goods is the fact that the fiscal policy will have no effect on the trade balance. The trade balance surplus will depend only on the nominal price of traded goods.

We conclude that we can represent the home country's real trade balance surplus $\overline{B}$ as an increasing function of the nominal price of traded goods P:

$$\overline{B} = \overline{B}(P) \tag{6}$$

By an identical line of argument the foreign country's real trade balance surplus $\overline{B}^*$ is an increasing function of the foreign nominal price of traded goods P^*.

$$\overline{B}^* = \overline{B}^*(P^*) \tag{7}$$

Finally the nominal prices of traded goods are related by the exchange rate e:

$$P = P^*e \tag{8}$$

Given the policy of pegging the nominal prices of nontraded goods in both countries, an exchange rate change becomes a change in a real variable. Devaluation of the home currency raises the *relative* price of traded goods in terms of nontraded goods at home and lowers the *relative* price of traded in terms of nontraded goods abroad. In response to that change in relative prices, resources move into the traded goods sector at home while consumers substitute from traded goods to home goods. Abroad exactly the opposite move takes place: productive resources move to the home-goods sector while consumers substitute toward traded goods thus generating a trade balance surplus for the home country. The magnitude of the surplus and the relative price changes will depend on the substitutability between goods.

The equilibrium condition in the world traded goods market is that one country's excess supply of traded goods equal the other country's excess demand for traded goods. Using (6), (7), and (8) this equilibrium condition may be written as follows:

$$\overline{B}(P) = -\overline{B}^*(P/e) \tag{9}$$

Figure 3 shows the determination of the equilibrium in the traded goods market. The home country's excess supply of traded goods or trade balance surplus $\overline{B}(P)$ is drawn as an increasing function of the domestic currency price of traded goods. Similarly foreign excess demand for traded goods is shown as a decreasing function of the domestic price of traded goods for a given exchange rate e^0. Initial equilibrium obtains at a domestic price of traded goods P^0 where the world traded goods market is in equilibrium and trade is balanced. Returning to Figure 2, this implies that income equals expenditure in

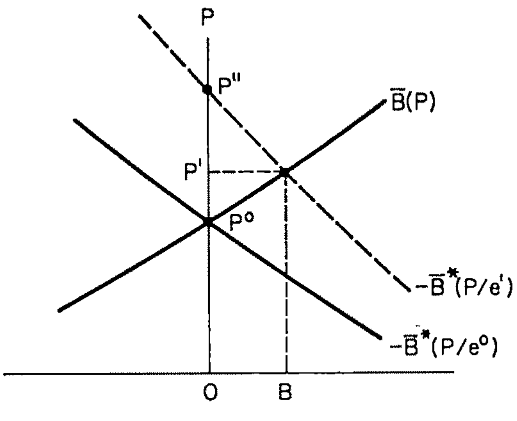

FIGURE 3

each country and that the home-goods market clears in both countries.

A devaluation by the home country will change the relation between domestic and foreign prices. In terms of Figure 3, the foreign excess demand schedule shifts upward in the proportion of the rate of devaluation. At the initial domestic currency price of traded goods P^0 there is a world excess demand for traded goods since the foreign price of traded goods has declined in the proportion as the exchange rate. In response to that excess demand the price of traded goods increases until the world market clears at a new domestic currency price P'. At that new price the home country has a trade balance surplus OB equal to the foreign country's deficit.

We note that the increase in the domestic price of traded goods $(P'-P^0)/P^0$ falls short of the rate of devaluation $(P''-P^0)/P^0$ which implies that the foreign price of traded goods has declined in the proportion $(P''-P')/P''$. It follows that a devaluation raises the domestic (relative) price of traded goods and lowers the foreign (relative) price of traded goods.

To appreciate why a devaluation exerts real effects, it is obviously necessary to go to the background of Figure 3 and study the fiscal policies that are triggered off by these price changes. In the home country, as was shown in Figure 2, the increase in the relative price of traded goods causes an excess demand for home goods which in turn is eliminated by an income tax collection equal to AB when measured in terms of traded goods. This implies that the counterpart of the trade balance surplus is an identically equal tax collection or budget surplus. It follows that the analysis is fully consistent with the absorption approach since it readily explains the decline in expenditure relative to income implied by the trade balance surplus. It follows, too, that in the absence of this fiscal policy the price of home goods would increase in response to the excess demand until relative prices returned to their initial position with no real effects persisting.

Consider next what happens in the foreign country. Abroad the nominal price of traded goods declines, and given the nominal price of home goods, the relative price of traded goods declines. In response to that relative price change there will be an excess supply of nontraded goods triggering off income transfers in order to restore equilibrium in the nontraded goods market. Figure 4 shows the new equilibrium in the foreign country with production at point A, consumption at point B, and a trade balance deficit equal to AB. The excess of expenditure over income or the income transfer measured in terms of traded goods is equal to the trade balance deficit.

Having shown that the domestic trade balance surplus is equal to income tax collections and that abroad the deficit equals the income transfers made by the government, it remains to infer from the equality of one country's deficit and the other country's surplus that a devaluation operates in the same manner as an international transfer from one country to another. Indeed, in this model a devaluation has exactly the same effects as a policy of transferring AB units of real income from the home country to the foreign country.

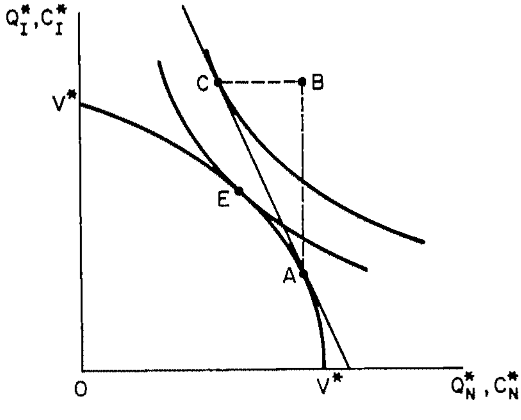

FIGURE 4

The preceding discussion can be formalized with the help of a few definitions. The real trade balance measured in terms of exportables is equal to the supply of exports less the demand for imports measured in terms of exportables:

$$(6') \quad \bar{B}(P) \equiv X(P_x) - (P_m/P_x)M(P_m)$$

where we assume that P_m/P_x is constant so that by an appropriate choice of units we have $P_m = P_x = P$. Similarly the foreign trade balance surplus $\bar{B}^*$ is defined by

$$(7') \quad \bar{B}^*(P^*) \equiv (P_m^*/P_x^*)X^*(P_m^*) - M^*(P_x^*)$$

Next we define the *compensated* elasticities of demand for imports and supply of exports:

$$(10) \quad \hat{M} = -\eta\hat{P}_m; \qquad \hat{X} = \epsilon\hat{P}_x;$$

$$\hat{M}^* = -\eta^*\hat{P}_x^*; \qquad \hat{X}^* = \epsilon^*\hat{P}_m^*$$

where a ˆ denotes a proportional change in a variable.

Using these definitions, assuming initial trade balance equilibrium and constant terms of trade, we can define the elasticity of the trade balance surplus or the excess supply of traded goods with respect to the relative price of traded goods in terms of home goods:

$$(11) \quad \frac{d\bar{B}}{dP}\,\frac{P}{X} = \sigma \equiv \epsilon + \eta;$$

$$\frac{d\bar{B}^*}{dP^*}\,\frac{P^*}{M^*} = \sigma^* \equiv \epsilon^* + \eta^*$$

We can now differentiate the equilibrium condition in (9), and using the definitions in (11) we derive the effect of a devaluation on the domestic (relative) price of traded goods:

$$(12) \quad \hat{P} = \frac{\sigma^*}{\sigma + \sigma^*}\,\hat{e}$$

Differentiating equation (8) and substituting from (9) yields the effect of a devaluation on the foreign price:

$$(13) \quad \hat{P}^* = \frac{-\sigma}{\sigma + \sigma^*}\,\hat{e}$$

We note from (12) and (13) that the distribution of price changes between countries will depend on the substitutability between traded goods and home goods in the two countries.

To determine the effect of the devaluation on the home country's trade balance we differentiate (6'), and using (11) and (12) we have:

$$(14) \quad d\bar{B} = X\,\frac{\sigma\sigma^*}{\sigma + \sigma^*}\,\hat{e}$$

Equation (14) shows that a devaluation unambiguously improves the trade balance of the devaluing country, and thus confirms the results derived in Figure 3.

The fact that a devaluation cannot worsen the trade balance distinguishes this composite traded good version most fundamentally from the more general form of the *BRM* model. It points out that the possibility of a worsening of the trade balance is not due to a devaluation per se, but rather to the terms of trade changes that may accompany a devaluation. The model developed here emphasizes, too, that as long as the terms of trade remain unchanged the scope for "elasticity pessimism" is very limited. We note from (14) that at worst a devaluation will leave the trade balance unchanged, a circumstance that arises if in either country there is zero substitutability between home goods and traded goods.

In concluding this section we remark that the essential elements of the *BRM* model are contained in the present version that maintains constant the terms of trade. These essential elements are that a devaluation changes the relative price of traded goods in terms of home goods thereby generating a surplus in the devaluing country and a deficit abroad. The counterpart of the change in the trade balance arises in the home-goods markets: an excess demand at home and an excess supply abroad. It is essential to the success of a devaluation that there be an "internal balance" policy that validates the relative price changes by a reduction in absorption at home and an increase in absorption abroad.

The fact that terms of trade changes are "almost" secondary in their role in this context has been recognized by I. F. Pearce (1961) and June Flanders who emphasize both the requirement of absorption changes and the change in the relative price of traded goods in terms of home goods. Regrettably, the terms of trade may change, and therefore a more complicated analysis is called for.

III. The Terms of Trade, Transfers, and the Trade Balance

The preceding analysis showed that at constant terms of trade a devaluation has the same effects as an income transfer: it lowers domestic absorption and increases foreign absorption where the magnitude of the absorption change is identically equal to the trade balance surplus shown in (14). In deriving the equilibrium change in absorption we have assumed that the world market for traded goods clears; we have not, however, shown that the market for each individual good will clear.

To determine whether the analysis in Section II is in fact consistent with equilibrium in each individual traded-goods market, it is sufficient to consider equilibrium in one of these markets. This is so since the preceding analysis called for clearing of the world traded-goods market so that by implication the excess demand in any one market would be offset by the excess supply in the other market. Without loss of generality we can conduct the analysis in terms of the market for the home country's importable. We will use the results of Section II to compute the change in domestic import demand and foreign export supply and determine whether they are exactly equal so that no change in the terms of trade is called for.

The change in the equilibrium price of importables, at constant terms of trade, is given by (12). Using the definition of the elasticity of demand for imports in (10) and substituting for the price change from (12) we have:

$$\hat{M} = -\eta\hat{P}_m = -\eta\frac{\sigma^*}{\sigma+\sigma^*}\hat{e} \tag{15}$$

The change in the foreign supply of exports is similarly derived by using the definition of the elasticity of supply in (10) and the equilibrium price change in (13), noting that $\hat{P}^*_m \equiv \hat{P}^*$.

$$\hat{X}^* = \epsilon^*\hat{P}^*_m = -\epsilon^*\frac{\sigma}{\sigma+\sigma^*}\hat{e} \tag{16}$$

The world excess demand for importables, at constant terms of trade, is given by the difference between (15) and (16), which with some manipulation may be written as:

$$dM - dX^* = X\frac{\sigma\sigma^*}{\sigma+\sigma^*}\left[\frac{\epsilon^*}{\epsilon^*+\eta^*} - \frac{\eta}{\epsilon+\eta}\right]\hat{e} \tag{17}$$

The home country's terms of trade will worsen or improve as there is at constant terms of trade a world excess demand or supply for importables, that is depending on the familiar Robinson criterion:

$$\epsilon\epsilon^* - \eta\eta^* \gtrless 0 \tag{18}$$

Equation (17) has a ready interpretation in terms of the transfer problem. The term $X\sigma\sigma^*/(\sigma+\sigma^*)$ measures the change in absorption or the change in the trade balance that is induced by a devaluation at constant terms of trade. In the home country the trade balance surplus is achieved through a reduction in imports and an increase in exports. The fraction of the reduction in absorption or the improvement in the trade balance that is reflected in reduced imports is $\eta/(\epsilon+\eta)$. Abroad the increased absorption and worsened trade balance is reflected in part in a decreased level of exports. The term $\epsilon^*/(\epsilon^*+\eta^*)$ measures the fraction of the increased absorption that is reflected in decreased exports. These fractions are not marginal propensities to spend that we ordinarily encounter in the discussion of the transfer problem, but they do play exactly the same role in that they indicate the effect of a change in absorption on individual commodity excess demands.[12] The channel here is not a direct expenditure effect measured by a marginal propensity, but rather a substitution effect that derives from the change in the equilibrium relative prices of home goods occasioned by the change in absorption that at constant relative prices falls entirely on these goods.

The preceding discussion shows that there is no presumption whatsoever about the direction in which a devaluation, or a transfer for that matter, will change the terms of trade. This point deserves emphasis since there continues to be the belief that a devaluation in and of itself changes the terms of trade. If a devaluation does, however, change the terms of trade the effects on the trade balance are no longer described by (14), but have to be derived from the disaggregated model in (1) to (5). Differentiating equations (1), (2), (4), and (5) and using the definitions in (10) yields the effects of a devaluation on the domestic prices of importables and exportables:

$$\hat{p}_m = \frac{\epsilon^*}{\epsilon^* + \eta}\hat{e}; \qquad \hat{p}_x = \frac{\eta^*}{\epsilon + \eta^*}\hat{e} \tag{19}$$

Differentiating the trade balance equation in (3) and substituting the equilibrium price changes from (19) gives the trade balance effect of a devaluation:[13]

$$dB = P_xX\left[(1+\epsilon)\frac{\eta^*}{\epsilon+\eta^*} - (1-\eta)\frac{\epsilon^*}{\epsilon^*+\eta}\right]\hat{e} \tag{20}$$

which with some manipulation may be rewritten in the more familiar *BRM* form:

$$dB = P_xX\left[\frac{\eta\eta^*(1+\epsilon+\epsilon^*) - \epsilon\epsilon^*(1-\eta-\eta^*)}{(\epsilon+\eta^*)(\epsilon^*+\eta)}\right]\hat{e} \tag{20'}$$

Inspection of (20) shows that if the terms of trade remain unchanged or improve, $\eta^*/(\epsilon+\eta^*) \geq \epsilon^*/(\epsilon^*+\eta)$, a devaluation will improve the trade balance. A worsening of the terms of trade, however, brings about the possibility of a worsening of the trade balance.[14] The interpretation of that possibility is as follows: The increase in the relative price of both traded goods in terms of home goods shown in (19) generates a substitution effect that induces a trade surplus and an excess demand for home goods. Against this substitution effect operates the income effect of a terms of trade deterioration which generates an excess supply of nontraded goods and a trade deficit. Similarly abroad the decline in the relative price of traded goods generates an excess supply of home goods on account of the substitution effect while the income effect of the foreign terms of trade improvement generates an excess demand. Whether the trade balance improves or worsens will depend on the relative size of the income and substitution effects. A more than sufficient condition is that in either country, the compensated elasticity of demand for imports be larger than unity —a condition that ensures that substitution effects dominate income effects.

---

[12] For a discussion of the transfer problem in a more general model with nontraded goods, see Ian McDougall, Pearce (1961, 1970), and Jones (1974).

[13] The reader will note that for the constant terms of trade case equation (20) reduces to (14) by using the substitution $\eta\eta^* = \epsilon\epsilon^*$.

[14] Jones (1974) has developed the interpretation of the *BRM* condition in terms of the stability of the underlying commodity markets.

The above argument shows, too, why a devaluation cannot worsen the trade balance when it improves the terms of trade. In this event both substitution effects and income effects operate in the same direction generating an excess demand for nontraded goods and as its mirror image a trade surplus; abroad, similarly, both the income and substitution effects operate in the same direction to generate an excess supply of nontraded goods and a corresponding trade deficit. Furthermore, if the terms of trade remain unchanged there are only substitution effects and hence an unambiguous improvement in the trade balance.

The possibility that a devaluation worsens the trade balance cannot be ruled out on theoretical grounds. Before taking alarm at that contingency, however, it is worth noting what the implications for the nontraded goods markets are. If that should not be sufficient to discourage "elasticity pessimism," it should still be borne in mind that the model contains some assumptions that may be inordinately strong, in particular, the unit marginal propensity to spend on home goods and the zero cross elasticity between traded goods.

IV. An Alternative Interpretation

In his discussion of the elasticity approach, Alexander pointed out that the import and export equations of the *BRM* model could be viewed as reduced forms that embody the effects of the absorption policies pursued in the background and where these effects are not necessarily limited to substitution effects as we have assumed so far. On this alternative interpretation the elasticities are no longer compensated elasticities but rather "total" elasticities, and it becomes important to know what effects they embody. One rather straightforward interpretation suggested by the analysis of Section II is developed here. On the assumption that the terms of trade remain constant we can interpret the response to a change in the price of traded goods as composed of both a substitution effect and an expenditure effect. The expenditure effect derives now from the assumption that the marginal propensity to spend on traded goods is positive so that the fiscal policies pursued in the background exert a direct effect on the trade balance.

The trade balance surplus can now be written as a function of the (relative) price of traded goods and disposable income $Y-T$, where Y and T denote respectively the value of output and taxes both measured in terms of home goods:[15]

$$\tilde{B} = \tilde{B}(P, Y - T) \tag{21}$$

Differentiating (21) and using (11) we have:[16]

$$d\tilde{B} = \sigma X\hat{P} + (1 - \pi)dT/P \tag{22}$$

where $(1-\pi)$ denotes the marginal propensity to spend on traded goods.

As was shown in Section II the trade surplus is equal to the change in absorption which in turn is equal to the change in taxes. We can therefore equate in (22) the terms $d\tilde{B}=dT/P$ to obtain the reduced form elasticity of the trade balance with respect to the relative price of traded goods:[17]

---

[15] The value of output measured in terms of home goods is defined as $Y=PQ_I+Q_N$.

[16] A change in the relative price of home goods has no income effect since demand equals production. Accordingly (22) only reflects substitution effects and absorption effects of a tax change.

[17] The equality of the change in the trade balance and in taxes is derived from the budget constraint. The value of expenditure equals the value of output less taxes: $PC_I+C_N=PQ_I+Q_N-T$ or $P(Q_I-C_I)+(Q_N-C_N)=T$. When the home-goods market clears, $Q_N=C_N$, the trade surplus is equal to taxes or $\tilde{B}=(Q_I-C_I)=T/P$.

$$d\tilde{B}/X = (\sigma/\pi)\hat{P} \equiv \bar{\sigma}\hat{P} \tag{23}$$

We note that (23) differs from (11) by the term in the denominator and reduces to (11) if the marginal propensity to spend on home goods, π, is unity. The direct expenditure effects on traded goods exerted by the fiscal policy raises the trade balance effects of a relative price change.

Proceeding in a similar manner for the foreign country we derive the reduced form elasticity $\bar{\sigma}^* \equiv \sigma/\pi^*$. Substituting the terms $\bar{\sigma}$ and $\bar{\sigma}^*$ in (14) instead of the terms σ and σ^* yields the trade balance effect of a devaluation with positive marginal propensities to spend on traded goods:

$$d\tilde{B} = X\frac{\sigma\sigma^*}{\sigma\pi^* + \sigma^*\pi}\hat{e} \tag{24}$$

Equation (24) shows that the trade balance effects of a devaluation are larger the smaller the marginal propensities to spend on home goods in each country. The reason is simply that if less of a tax change falls on home goods then larger tax changes are required in order to maintain home-goods market equilibrium when the relative price of home goods is changed by an exchange rate change. Equation (24) therefore serves to highlight the role of the absorption policies in the *BRM* model.

So far the analysis has assumed that fiscal policy is used in each country to maintain constant the nominal price of home goods. This is certainly not the only interpretation of total elasticities. An alternative that has been widely referred to is the assumption that nominal income is maintained constant. This would require that an increase in the nominal price of traded goods be accompanied by a decline in the nominal prices of home goods. Assuming that fiscal policy maintains constant the nominal value of income, we have the following relationship between price changes:[18]

$$\hat{P}_N = -[(1-\theta)/\theta]\hat{P} \tag{25}$$

where $\hat{P}_N$ denotes the proportional change in nominal home-goods prices, and where θ denotes the share of home goods in nominal income.

The trade balance effect of a change in the nominal price of home goods is now composed of three elements: The substitution effects induced by a rise in traded goods prices (relative to home-goods prices) and the accompanying decline in home-goods prices and the effect of the fiscal policy required to maintain home-goods market equilibrium at a constant nominal income. We can therefore rewrite the trade balance effect of a change in the *nominal* price of traded goods as:

$$d\tilde{B}/X = \bar{\sigma}(\hat{P} - \hat{P}_N) = (\sigma/\pi\theta)\hat{P} \tag{26}$$

where we have substituted for the home-goods price change from (25).

Equation (26) shows that the trade balance effect of an increase in the nominal price of traded goods is inversely proportional to the share of home goods in nominal income. This is so because by (25) the smaller the share of home goods, the larger the change in the relative price of traded goods induced by a change in their nominal price, $\hat{P} - \hat{P}_N = (1/\theta)\hat{P}$. We can derive an expression analogous to (26) for the foreign country and substitute the reduced form or total elasticities, $\lambda \equiv \sigma/\pi\theta$ and $\lambda^* \equiv \sigma^*/\pi^*\theta^*$, in (14) to find that the effects of a devaluation on the trade balance are the larger the smaller the shares of home goods in nominal income, given a policy in each country of maintaining constant money income:

$$d\tilde{B} = X\frac{\sigma\sigma^*}{\sigma\pi^*\theta^* + \sigma^*\pi\theta}\hat{e} \tag{27}$$

---

[18] From the definition of nominal income $Y = PQ_I + P_NQ_N$, we derive equation (25) by differentiation. A policy that maintains constant nominal income is equivalent to maintaining constant a price index $\bar{P} = P^{(1-\theta)}P_N^{\theta}$. For a further discussion, see the author (1974) and Pearce (1970). Since the nominal price of home goods now is flexible, P only denotes the nominal price of traded goods.

A comparison of equations (24) and (27) shows that the real effects of a devaluation depend crucially on what nominal variables are held constant. Thus a policy of maintaining constant the nominal prices of home goods generates a smaller trade surplus than one that maintains constant nominal income. Since exchange rate changes exert real effects because they constitute changes relative to some other nominal variable, it is indispensable to ask what that variable is in order to determine the nature and magnitude of the response to an exchange rate change.

V. Concluding Remarks

This paper has developed an interpretation of the *BRM* model that gives emphasis to the general equilibrium context in which the analysis of the traded-goods markets has to be placed. Such a general equilibrium model will involve a market for home goods and an explicit policy of maintaining constant some nominal variable. That policy provides the link with the absorption approach. Comparison of alternative policies shows that the real effects of an exchange rate change depend critically on the choice of nominal variables to be pegged. It points out, too, that there is not much use in considering reduced form equations without making explicit the general equilibrium and macroeconomic system from which they are derived.

Equities, Capital Gains, and the Role of Finance in Accumulation

By B. J. Moore*

The purpose of the present paper is to develop some implications of the introduction of corporate equities and capital gain income into macro-economic growth models. Capital gains received by wealth owners are shown to be related to the volume of corporate retentions and to the valuation ratio, the latter defined as the ratio of the market value of ownership claims on property income to the market value of real assets.[1]

Retained earnings and capital gains are a large and volatile component of a broadly defined measure of total personal income. It is surprising that most previous studies of household consumption and saving behavior have not dealt explicitly with either retained earnings or capital gains. A Keynesian approach, which includes disposable income and wealth as variables in the consumption function, distinguishes sharply between dividend income and retained earnings. In contrast a Fisherian approach, which describes consumption as the allocation of an individual's wealth over his lifetime, treats all property income the same way, and implies that the allocation of profits between retained earnings and dividends has no effect on aggregate saving. Both views represent the consequences of specifying consumer behavior without sufficiently considering the implications of the corporate form of business, and the distinction between labor and property income. The present paper argues that the propensity to consume out of capital gain income plays a critical role in the Keynesian-neoclassical controversy concerning the independence of investment from saving behavior.[2] The paper closes with some implications of the argument for the role of finance in the process of capitalist accumulation and for the theory of interest.

I. Equities and Capital Gains in a Macro-Economic Growth Model

In conventional growth models golden age defines a path in which output, capital stock, and effective labor (assuming constant returns to scale and Harrod-neutral technical progress) all grow at the same constant rate g. Such a balanced growth path represents a moving equilibrium configuration only if the wealth propensities of the society are satisfied as well as the saving, investment, and technological requirements. If k is the capital-output ratio, the share of output that must be saved and invested in new capital is gk. But it is not self-evident that the desired wealth-income ratios of wealth owners are such as to maintain the required capital-output ratio.

---

* Professor of economics, Wesleyan University. I would like to express my indebtedness to conversations with Paul Davidson, Mike Lovell, and Joan Robinson, none of whom is in any way inculpated by the ideas presented below. The paper was conceived while I was a Senior Visitor to the Economics Faculty at Cambridge, on sabbatical leave from Wesleyan.

[1] The use of the valuation ratio as a macro-economic concept was first introduced by Nicholas Kaldor (1966) in his "Neo-Pasinetti Theorem."

[2] For a presentation of modern growth theories which emphasizes the centrality of this distinction, see Jan Kregel. Recently Franco Modigliani has revised the *FMP* model to emphasize the role of consumption out of capital gains in the transmission mechanism of monetary policy. See also Paul David and John Scadding.

While the latter is conventionally stated in terms of saving, growth, and technological requirements, economic units in the aggregate must simultaneously be willing to own and accumulate the resulting capital stock.

In a one-asset world, physical capital is identical to private wealth and real investment is identical to saving. In golden age growth the desired wealth-income ratio is the same as the required capital-output ratio, and the desired saving-income ratio is identical to the required investment-output ratio. With the introduction of financial assets and government or foreign sectors, total private wealth may diverge from the capital stock, and private saving from capital formation. The government or the rest of the world may own a share of the economy's capital stock, or may issue "outside" financial assets that can satisfy private demand for wealth and saving. A number of authors have introduced money and bonds into growth models to illustrate how government financial policy can alter the golden age path that simultaneously satisfies technological requirements and thrift propensities.[3]

The introduction of corporate equities represents an alternative mechanism by which wealth-income and capital-output ratios can diverge. Consider a model in which all real capital K is owned by business corporations and financed solely by the issue of stock. Corporations are intermediate wealth entities, owned ultimately by households. Assume for simplicity that corporate equities are the only type of financial assets, so that total household wealth W is held in the form of equities. If E is the price of equities and N the number of equities in existence:

$$W \equiv EN \tag{1}$$

Total household wealth W bears some relationship v to the value of the real capital stock K owned by corporations $v=W/K$. The valuation ratio v represents the ratio of the market value of ownership claims to corporations (the present value of expected future income from share ownership) to the market value of corporate real assets:

$$W \equiv vK \tag{2}$$

Differentiating with respect to time

$$dW \equiv dN \cdot E + dE \cdot N \tag{3}$$

$$dW \equiv dK \cdot v + dv \cdot K \tag{4}$$

where d represents the net change in the variable over the time interval considered.[4]

Total net output and income in any period consists of labor income L received by households, and property income P received initially entirely by corporations. If s_B is the corporate retention ratio, retained earnings are s_BP, and dividends paid to household shareowners are $(1-s_B)P$. Corporate net investment, the change in the real capital stock $I=dK$, may be financed internally out of retained earnings s_BP or externally from new share issue $(E \cdot dN = iI)$ where i represents the proportion of net investment financed externally.

$$I \equiv s_BP + E \cdot dN \equiv s_BP + iI \equiv dK \tag{5}$$

From equations (3), (4), and (5) an expression may now be derived for capital gains G:

$$\begin{aligned} G &\equiv N \cdot dE \equiv dW - E \cdot dN \\ &\equiv s_BP + (v-1)dK + K \cdot dv \end{aligned} \tag{6}$$

Capital gains are equal to corporate retained earnings s_BP plus corporate net investment times the excess of the valuation ratio over unity $(v-1)dK$, plus or minus capital gains or losses due to changes in the valuation ratio in the period $K\cdot dv$. For the case in which the productivity of new investment is equal to the discount rate applied to future income from share ownership, v will equal one, so that corporate retentions will result in an accrual in share values equal to the capital gain income to stockholders.

---

[3] For a summary of this literature, see Jerome Stein.

[4] Equations (3) and (4) hold only as approximations and only when the changes are small. The exact expressions require the addition of the term $dN \cdot dE$ to equation (3) and $dK \cdot dv$ to equation (4). Stock splits are ignored so that N changes only with new issues. For a more extended analysis of the introduction of corporate equities and capital gains into macro-economic growth models, see the author (1973a).

Household comprehensive income, the net accretion of economic power over any period, is equal to labor income, dividends, and capital gains:

$$\begin{aligned}(7)\quad Y_H^c &\equiv L + (1 - s_B)P + G\\ &\equiv L + P + (v-1)dK + K\cdot dv\end{aligned}$$

Corporate retention policy thus determines only the form in which household income is received between dividends and capital gains. All income earned by corporations, whether paid out or retained, is simultaneously comprehensive income to household shareowners. Business retentions thus exert a potentially expansionary influence on aggregate demand, depending on household propensity to consume out of capital gain income. They represent income available to be spent twice, first as retained earnings of businesses which may be spent on investment goods, and then as capital gain income to household capitalists, which may be saved or spent on consumption goods.

Total comprehensive income of the household and business sector Y^c is equal to current output plus capital gains. For accounting consistency, comprehensive output must be redefined to include capital gains. Saving out of comprehensive income S^c is equal to investment plus capital gains. Saving represents a decision to accumulate wealth, and can be satisfied by real asset accumulation or by the revaluation of existing assets:

$$\begin{aligned}(8)\quad Y^c &= Y + G = L + P + G\\ &= C + I + G\\ (9)\quad S^c &= S_B^c + S_H^c = I + G\\ &= s_B P + vI + K\cdot dv\\ (10)\quad S_H^c &= vI + K\cdot dv = iI + G\end{aligned}$$

The rate of growth of share prices is equal to:

$$\begin{aligned}(11)\quad \frac{dE}{E} &= \frac{dK}{K} - \frac{dN}{N} + \frac{dv}{v}\\ &= \frac{dK}{K}\left(1 - \frac{i}{v}\right) + \frac{dv}{v}\end{aligned}$$

When the valuation ratio remains constant $(dv=0)$, this is identical to the rate of growth of dividends per share. If corporate investment is expected to grow at the constant rate g in perpetuity $(g=I/K = dK/K)$, and future dividend and capital gain income is discounted at the constant rate r, this leads to the valuation formula:

$$(12)\quad E = \frac{(1 - s_B)P/N}{r - g\left(1 - \frac{i}{v}\right)}$$

Rewriting

$$(13)\quad r = \frac{(1 - s_B)P}{EN} + g\left(1 - \frac{i}{v}\right)$$

$$\begin{aligned}(13')\quad r &= \frac{P}{EN} + g\left(\frac{v-1}{v}\right)\\ &= \frac{1}{v}\left[\left(\frac{P}{K}\right) + g(v-1)\right]\end{aligned}$$

The discount rate and so the rate of return on equities is equal to the dividend yield plus the rate of growth of dividends per share. Alternatively the return on equities is equal to the earnings-price ratio plus the expression $(v-1)/v$ times the growth of corporate assets, which will be positive, zero, or negative depending on whether $v \gtreqless 1$. When $v=1$ the discount rate on shares is simply equal to the profit rate, and so the rate of return on investment.

II. Wealth-Income Ratios in Balanced Growth

The introduction of equities permits the value of private wealth to diverge from the value of the capital stock, so that saving diverges from real capital accumulation. If capital investment grows autonomously at the rate g $(I=gK)$, it is possible to formulate the relationship between private wealth and the real capital stock in balanced growth. A necessary condition for balanced growth is that the profit rate $(\pi=P/K)$, the rate at which the stock market discounts future income r, and the valuation ratio v remain constant. In this case $dv=0$, and capital gains and wealth accruals are equal to $G=s_BP+(v-1)gK$.

Assume first that households save some constant proportion (s_H) of their comprehensive income. The household saving function may be written:

$$(14)\quad \overset{o}{S_H} = s_H[L+(1-s_B)P+G] = s_H[Y+(v-1)I]$$

In balanced growth comprehensive saving and investment must be equal, so that it is possible to solve for the equilibrium value of v:

$$(15)\quad s_BP+s_H[Y+(v-1)I] = I+G = I+s_BP+(v-1)I$$

$$(15')\quad s_H[Y+(v-1)I] = vI$$

$$(16)\quad v = \left(\frac{s_H}{1-s_H}\right)\left(\frac{Y-gK}{gK}\right)$$

$$\frac{\partial v}{\partial s_H} > 0, \quad \frac{\partial v}{\partial g} < 0, \quad \frac{\partial v}{\partial\left(\frac{K}{Y}\right)} < 0$$

The valuation ratio, which expresses the wealth-capital ratio W/K, is positively related to household saving preferences, and negatively related to the growth rate and to the capital-output ratio. If investment is autonomous, and if household saving is independent of income form, corporate retention policy is irrelevant and has no effect on any real variables, but only determines the form in which household comprehensive income is received between dividends and capital gains. The valuation ratio will be greater or less than one depending on whether the household saving ratio out of comprehensive income is greater or less than the investment income ratio of business corporations ($v \gtrless 1$ according to whether $s_H \gtrless gK/Y$).

Household saving is in fact dependent on the form in which income is received.[5] Assume that the household saving function may be written:

$$(17)\quad \overset{o}{S_H} = s_LL+s_P(1-s_B)P+s_GG$$

where $1 \geq s_G \geq s_P \geq s_L \geq 0$.

The equilibrium value of v then becomes

$$(18)\quad v=\frac{s_LY+(s_P-s_L)P+(s_G-s_P)s_BP-s_GgK}{gK(1-s_G)}$$

$$\frac{\partial v}{\partial s_L}>0, \quad \frac{\partial v}{\partial s_P}>0, \quad \frac{\partial v}{\partial s_G}>0,$$

$$\frac{\partial v}{\partial s_B}\geq 0, \quad \frac{\partial v}{\partial g}<0, \quad \frac{\partial v}{\partial K}<0$$

The valuation ratio now depends positively on household and business saving propensities. The effect on v of corporate retentions depends on the size of the differential $(s_G - s_P)$, so that the effect on v of the share going to property depends on the differential $(s_P - s_L)$. New issues by firms will lower total saving and the valuation ratio so long as household saving out of capital gains exceeds saving out of dividend income $(s_G > s_P)$.

---

[5] Several empirical studies have estimated that the propensity to consume property income is less than the overall propensity to consume (see Lawrence Klein and Arthur Goldberger, Robert Holbrook and Frank Stafford). There have been few empirical studies of the effect of capital gains on consumption other than as a component of wealth, with a coefficient between 0.05 and 0.01 (see John Arena, Kul Bhatia, Franco Modigliani). In a recent paper Martin Feldstein has estimated that the propensity to consume the retained earnings component of capital gains was 0.25, while capital gains in general have a much smaller effect (0.02) on current consumption.

Empirical studies indicate that only a small proportion of capital gains and losses are realized (see Martin Bailey, Bhatia), and that the volume of unrealized gains has little impact on household consumption expenditures (see Arena). Alternatively expressed, the propensity to save out of capital gain income is extremely high $(s_G > .95)$. This suggests that changes in equity prices and in v must operate primarily through their effect on investment expenditures rather than consumption expenditures in order to restore equilibrium in the market for current output.

A. *The Significance of the Valuation Ratio*

Equations (16) and (18) state an extremely important relationship. Since households are the ultimate wealth owners under the institution of private property, the total value of the economy's wealth held in household portfolios must adjust until it satisfies the amount households desire to hold, which is in turn related to their (lifetime) income, the growth rate, and their saving preferences. So long as investment expenditures are autonomous and independent of financial forces, a change in household saving preferences by assumption cannot affect the rate of real capital formation. An autonomous rise in household saving propensities would result solely in a rise in the valuation ratio, and so in the ratio of comprehensive income to current output. So long as $s_G < 1$ this would raise household consumption expenditures as a proportion of current output, until equilibrium in the goods and security markets had been restored. As shown by equation (15′) v must adjust until household saving out of comprehensive income is equal to v times the rate of corporate real investment.

The introduction of equities and capital gains thus provides an additional escape from the Harrod-Domar knife-edge dilemma. In the simplest formulation $S = sY$ and $I = gK$, so that for full employment equilibrium investment and output must grow at the warranted rate $g_w = s/(K/Y)$. The neoclassical solution is to introduce a production function with variable factor proportions, so that the capital-output ratio K/Y adjusts over the long run to saver preferences to ensure that the warranted equals the natural rate. The neo-Keynesian solution is to introduce two sectors, capitalists and workers, with different saving propensities, so that the distribution of income between labor and property, the rate of profit, and the aggregate saving ratio(s) adjust to ensure equality of the warranted and natural rate (see Nicholas Kaldor, 1956). In the present capital gains model the valuation ratio, the ratio of wealth to income, the relation between comprehensive income and current output, and hence the proportion of current output consumed, adjust to satisfy full employment balanced growth. While the capital-output ratio may be technologically determined, the ratio of wealth to income, and hence the value of claims to the capital stock, is governed by saving preferences, since it must be consistent with the amount that wealth owners desire to hold. Saving represents the demand to accumulate assets, and these may be provided by real capital accumulation or by the revaluation of existing assets.

Changes in v thus introduce an additional stabilizing factor into the model, in the sense of an additional adjustment mechanism to equate planned saving by households and planned investment by corporations. If households desire to save more than corporations plan to invest, the result is to raise v and the value of wealth portfolios ($W=vK$), and thus provide the increase in wealth values that households desire. The deflationary implications of a rise in household savings are offset by a higher v and a higher ratio of comprehensive income and so consumption to current output. Conversely a decision by households to save less and accumulate wealth at a lower rate need not necessitate a lower rate of accumulation of real capital, but merely a reduction in v. An excess of planned investment over planned saving causes v to fall to a lower level, reducing household comprehensive income and so offsetting the expansionary pressures of a rise in investment expenditures. A change in v thus results in higher or lower recurring capital gains or losses being generated in the growth process. The level of v as well as changes in the level act as a governor to maintain equilibrium in the markets for securities and current output.

While capital gains or losses created by a rise or fall in security prices may be an important contributory factor to the climate of business expectations in which investment decisions are formed, the main influence of v on investment spending comes through changes in the discount rate implicit in security prices as the present value of an expected future stream of dividend and capital gain income (equations (13) and (13′)). Fisherian firms intent on maximizing share values will take the discount rate implicit in share prices as the required cutoff rate of return on investment. Corporations would expand the rate of investment when $v>1$, and reduce it when $v<1$.[6] With endogenous investment, v would have a long-run equilibrium value lying around unity, where the upper and lower bounds are defined by the degree of managerial independence and imperfections in the market for corporate control.

Table 1 presents empirical estimates of the market value to book or replacement value of corporate equity in the postwar period. As may be seen corporations do not adjust investment spending sufficiently to maintain this ratio equal to one in the short run. But the ratio of market to book or replacement value of corporate equity is a poor measure of the valuation ratio as defined in this paper. Replacement value is estimated by reference to historical costs and depreciation conventions. Market value of equity represents the discounted present value not merely of earnings from real capital as measured in the denominator, but also earnings due to technological change, monopoly rents, research and development, good will, and the skill and experience of the firm's labor force and management. As a result, investment expenditures are not well explained by movements in the ratio of market to replacement value of corporate equity.

III. Differential Wealth-Income Ratios: The Importance of Inequality

Saving represents the amount of current income devoted to asset accumulation. But in balanced growth the latter is simply equal to initial wealth times its rate of growth. If S_H^c represents total household saving out of comprehensive income, the average saving ratio as a proportion of current output may be expressed $s=S_H^c/Y$. If the growth rate of income and wealth are exogenous, the economy's wealth-income ratio depends directly on households' average saving ratio as a proportion of current output, and thus on the functional distribution of income and saving propensities by income form.

---

[6] Since this is a one-good model the problem of finding a price for the capital stock over time does not arise. The absence of a relative price for capital goods prevents instantaneous arbitrage of the valuation ratio equal to unity by corporate investment decisions.

TABLE 1—HISTORICAL ESTIMATION OF THE VALUATION RATIO NONFINANCIAL CORPORATE NET WORTH

A. United States 1900–58 (Billions of Dollars)

Year	Market Value	Book Value	Valuation Ratio[a]
1900	14.7	22.2	66.2
1912	39.3	37.7	104.2
1922	76.1	95.1	80.0

C. United Kingdom 1957–61 (Billions of Pounds)

Year	Market Value	Book Value	Valuation Ratio[a]
1957	11.3	26.6	42.5
1958	15.0	28.2	53.2
1959	22.2	30.2	73.5
1960	21.2	32.8	64.6
1961	22.1	35.0	63.1

Sources: **A**: R. Goldsmith and R. Lipsey, Table 25, pp. 126–27; **B**: C. W. Bischoff; **C**: J. Revell, Table 3.7, p. 58.

[a] Shown in percent.

$$s = \frac{S_H^c}{Y} = \frac{gW}{Y} \tag{19}$$

$$\frac{W}{Y} = \frac{s}{g} = \frac{1}{g}\Bigg[s_L + (s_P - s_L)\left(\frac{P}{Y}\right) + (s_G - s_P)\left(\frac{s_B P}{Y}\right) + s_G\left(\frac{gK(v-1)}{Y}\right)\Bigg] \tag{20}$$

As stated the effect of business saving is potentially inflationary, since corporate retained earnings devoted to real capital accumulation become available as capital gains to be spent again by households. Shareholders always have the possibility of "undoing" by realizing as capital gains any forced saving undertaken for them by their corporate managers. The equilibrium wealth-income ratio in balanced growth is simply equal to the average saving ratio divided by the growth rate (equation (20)), and so cannot be higher than the amount households are willing to save and accumulate. Only if households always passively hold all wealth increments received

TABLE 2—WEALTH-INCOME RATIO BY WEALTH CLASS, 1962[a]

Source: Projector and Weiss, Tables A-8, A-16, A-33, A-36.

[a] Wealth is defined to include the following assets, measured at market value: homes, automobiles, businesses or professions, liquid assets, investment assets, and assets held in trust minus the value of debts secured by these assets, primarily home mortgages. Assets omitted are equity in life insurance, annuities and retirement funds, and personal durables: clothing, furniture, household and sports equipment, jewelry, art collections, coins, stamps, etc.

as capital gains due to corporate retentions ($s_G=1$) will corporate saving behavior never be undone by wealth owners. As shown in equation (18) this would imply that households have no desired finite wealth-income ratio.

As is well known, wealth ownership is highly concentrated. In the United States the most detailed study of upper income and wealth groups has estimated that the wealthiest 10 percent of consumer units accounted for about 65 percent of total household wealth (net of debt secured by these assets and excluding consumer durables other than automobiles) and over 90 percent of all publicly traded stock (see Dorothy Projector and Gertrude Weiss). As shown in Table 2 the wealth-income ratio rises dramatically by income level. The median wealth-income ratio for the lower 85 percent of households is considerably less than one. The composition of wealth portfolios is also sensitive to wealth and income levels. Lower wealth holders own primarily homes, consumer durables, automobiles, and some liquid assets. Top wealth owners hold the bulk of their wealth in the form of business and investment assets, primarily listed and unlisted corporate stock and equity in business and professions.

Since saving represents the demand to accumulate wealth, higher wealth-income ratios necessarily imply higher saving-income ratios if the wealth-income ratio is to be maintained over time. Consider the case of top wealth holders whose income is derived virtually entirely from property, so that their wealth-income ratio is $W/rW = 1/r = s/g$. Since the rate of growth of their wealth is simply the rate of return earned r_c times their saving ratio s_c, the rate of growth of their wealth is $g_c = s_c r_c$. In order to maintain their relative wealth share, their wealth must grow at the rate of growth of the economy. This implies that with rates of return on wealth about double the growth rate of the economy, capitalists would have to have a saving ratio of about 0.5. This in fact approximates the estimated saving ratios for upper income groups (see Simon Kuznets, Irving Friend and Irving Kravis).

This suggests the functional significance of highly concentrated property income and wealth ownership observed in all capitalist societies. If wealth were equally distributed, the economy's wealth-income ratio would be governed by the representative households' saving preferences. With life cycle-consumption behavior and zero terminal wealth bequests, the economy's aggregate wealth-income ratio would be much lower, as limited by the amount households desire to save during their working life to consume during their retirement.[7] Suppose that, after a revolution, all corporate stock were redistributed equally among households. Due to the attempt to realize these claims for consumption purposes, in particular real estate and consumer durables, on the part of many households, equity values would fall drastically. A new equilibrium position would eventually be reached at which the ratio of wealth and capital to income would be much lower, discount and profit rates higher, and investment and growth rates lower.

It is difficult to resist the conclusion that wealth concentration leads to "too much" saving and wealth, relative to what would occur with a more egalitarian distribution of wealth ownership, where household saving preferences would be more equally and therefore more democratically weighted in the market place. What has posterity done for us recently? With a more equal distribution of wealth ownership, a much greater bribe would have to be paid to wealth owners to induce them to refrain from present consumption and maintain any given ratio of wealth to income. When all wealth is concentrated in a few hands, a much smaller bribe is sufficient to induce wealth owners to forego additional present consumption, particularly when they are already consumption leaders.

IV. The Role of Finance in Accumulation: Saving as a Constraint on Investment

In the neoclassical view the rate of profit in the long run was regarded as determined simultaneously by technological relationships, which govern the marginal productivity of capital assets and lie behind the demand for loanable funds, and by time preference and thrift, which govern the saving function and so the supply of loanable funds. The interest rate as the price of hiring purchasing power fell somewhere between the real rental rate for capital goods and the return from holding money, return differentials measuring the risk and liquidity premiums associated with different assets. Interest had to be paid to savers as a reward to waiting, to induce them to defer present consumption and yield up their control of purchasing power to others.

The contribution of Keynesian analysis was to distinguish sharply the return on real assets from the return on fixed-income financial assets, and to weaken the link between them, at least in the short run in which real world economies are continually enmeshed. The interest rate as determined in financial markets reflected the outcome between portfolio preferences for liquidity and existing stocks of financial assets. The functional justification of interest was undermined, since interest was regarded as the reward for foregoing liquidity, noncommitted purchasing power, rather than foregoing present consumption of goods. Saving was regarded as inelastic to the rate of interest, which was strongly influenced by inelastic expectations based on past experience. The interest rate determines the present value of capital goods as the discounted value of their expected future earnings. If this exceeded their minimum supply price, net investment would occur. The rate of investment would depend on the elasticity of supply of the capital goods industries.

---

[7] James Tobin has calculated that with even the relatively low subjective discount rate of 5 percent, the aggregate demand for wealth by life cycle savers becomes negative, as high consumption in the early years is financed by borrowing against future income.

The Keynesian view tends to emphasize the autonomous nature of investment behavior in governing the rate of capital accumulation. The effect of greater investment spending is to generate the higher income, profits, and saving necessary to finance it. "Workers spend what they get, capitalists get what they spend" is Professor Kalecki's well-known aphorism. Investment decisions were made by business in response to anticipations of future profits. Corporations undertook some saving directly in the form of retained earnings, and the rest was generated indirectly by the rise in the level of income. As a result interest became more of a transfer payment, and was no longer viewed as a necessary reward for waiting or abstinence. Keynes was consequently able to visualize the future euthanasia of the rentier as the return on investment fell with increased capital accumulation.

The logic of the present argument in a sense supports both views. The neoclassical conclusions of the control of the rate of accumulation by saver preferences is validated in principle, albeit through a quite different mechanism. It is not necessary to pay interest to induce wealth owners to save and forego current consumption of goods. Business corporations will undertake both the investment and much of the saving necessary to finance it. Nor is interest needed to induce wealth owners to forego purchasing power. All financial claims could easily be invested with liquidity. Rather interest must be paid to induce wealth owners to hold voluntarily and not spend on current consumption the wealth accumulation that results from business investment. Assume that all corporate investments were internally financed. Corporate retentions do represent involuntary saving by corporate owners, undertaken by corporate managers, largely independently of the saving preferences of shareholders as the Keynesians have emphasized. Nevertheless the Keynesian view ignores the fact that holders of equities always have the possibility of "undoing" any such involuntary saving undertaken by their hired managers, simply by realizing for consumption purposes the capital gains that accrue from the investment process.[8]

The mechanism by which this control by wealth owners operates in the present model is through the valuation ratio. Even though wealth owners in the aggregate cannot enjoy more consumption goods than are currently being produced, the attempt to realize wealth and capital gains in order to purchase commodities drives down equity values. Fisherian firms will adjust their investment spending to maximize the equity value of the corporation, and this requires using the rate of discount implicit in share prices as the cutoff rate of return for investment projects. A fall in the valuation ratio raises the cost of capital, reducing the amount of investment undertaken. Such firms adjust investment spending until the valuation ratio is again equal to one, at which point, providing there is an inverse relationship between the return on real capital and the capital-output and capital-labor ratio, the wealth-income and investment-income ratio will have fallen and the output of consumption goods will have increased. The adjustment process takes time; so long as wealth owners cannot consume the existing capital stock directly, reduction comes about by not replacing depreciated capital goods and negative net investment.[9]

---

[8] Capital gains as stated introduce a potentially inflationary element into the economy. Corporate income spent on investment creates income *pari passu* to corporate owners, which can be spent over again for consumption. If wealth owners collectively do not wish to accumulate, they can realize their capital gains and prevent their wealth portfolios from increasing. It is frequently pointed out that the excess of disposable income over earned income due to capital gains rests on an illusion, since if wealth owners collectively decided to realize their gains, the gains would disappear. But it is not always recognized that the same illusion holds for wealth ownership of whatever sort. The stock of wealth represents value relationships in terms of current commodities. If wealth owners were unwilling to hold assets greater than a certain proportion of their annual income, the value of the existing wealth stock, irrespective of how large an inventory of physical assets is represented, must fall to this level. The fact that there is this element of illusion when viewed collectively does not alter the fact that from the viewpoint of the behavior of an individual, one dollar of accumulated wealth or of capital gains income is exactly equivalent to one dollar of earned income in its command over purchasing power. For the individual a high ratio of wealth to income offers potential disposal over goods far in excess of current income, even if this is impossible for the community as a whole.

The same general mechanism also operates for non-Fisherian firms in imperfect capital markets. In this case, rather than having a long-run equilibrium value of one, the valuation ratio would have some upper and lower bound. Within this range corporate decisions to accumulate would be independent of wealth owner preferences and rate of time preference. Only if corporations were completely indifferent to the market price of their stock would they be able to operate completely independently of wealth owner preferences as reflected in financial valuations.

V. Property Income and Economic Rent

While the argument thus leads to the validation of the neoclassical view of control of capital accumulation by saver preferences in principle, in practice as developed above ultimate wealth owners do not choose to undo the accumulation decisions of their corporate managers. If capital gains are always saved, the saving preferences of wealth owners are not a constraint on accumulation, apart from the influence of the valuation ratio in corporate investment. In the short run investment tends to create the saving necessary to finance it, and we are back in a Keynesian world.

Acceptance of such a view would seem to have profound implications for the functional justification of property income. Most of the economy's saving is undertaken by upper income groups, either directly or indirectly by their corporate managers and not undone. Such saving behavior would appear only to be explainable in terms of the satisfaction derived directly from possession and accumulation of wealth.[10] To the extent saving by such groups represents not a conflict between present and future consumption (using up), but the acquisition of long-lived goods yielding current and future satisfaction complimentarily, the traditional functional economic justification of interest as the reward for waiting, for the deferral of present gratification, largely disappears. To the extent that for capitalist households saving does not represent a choice between present versus future satisfaction, because wealth possession and accumulation yield present utility directly, a very large component of economic rent is involved in property income. To the extent asset acquisition for such groups in fact yields substantial services-in-kind, a much smaller or even zero income return would suffice as an inducement to forego absorptive expenditure and hold the economy's capital stock.

---

[9] In a one-good model it would be possible for wealth owners to control the stock of real capital directly in the short run. This would occur if firms bought and sold securities for goods so as to maintain the valuation ratio equal to unity, or any other level above or below one. Household desire to hold less wealth would result in open market purchases of equities by firms in return for commodities, so that households could consume some of the existing capital stock directly. Conversely household desire to hold more wealth would result in new issues of equities by firms in exchange for commodities, so that real capital accumulation would occur *pari passu*. With such a perfectly accommodating financial system aggregate demand would always equal full employment aggregate supply, since excess demand for commodities would never appear.

[10] For a criticism of life cycle-saving theories which emphasizes the distinction between labor and property income concerning the bequest motive for saving, see the author (1973b).

This does not of course imply that even with a zero reservation price of saving, a zero rate of return is possible or even appropriate, under capitalism or socialism. Financial returns like all prices have both an allocative and distributive effect (see James Meade). Some positive cost of finance is required to allocate scarce resources efficiently between alternatives. But from a distributional viewpoint property income is very largely a transfer payment from workers to owners, a quasi rent like the return to ownership of land, which apart from saving incentives has little economic justification as a reward to ownership per se. The fact that capital goods are productive cannot in itself be used to justify the assignment of their value contribution to their private owners, particularly if no economic sacrifice or burden or function is involved in the ownership and accumulation of such wealth. One of the unattractive apologist implications of conventional economic analysis is that it serves to elevate rents, profits, interest, and all property income to the level of respectability of wages (see Joan Robinson). Moreover property income, the quasi rents paid to the owners of claims against the product of past labor inputs, can only under very restrictive assumptions be regarded as measuring the marginal productivity of any "mythical" current capital stock.[11]

Consider the limiting case in which corporations rely entirely on internal finance for investment expenditures ($I=s_BP$) and households save all capital gains received from stock ownership ($s_G=1$, $s_L=s_P=0$). In such a world there would be no financial constraint on investment: saving by corporations and households would always be exactly sufficient to finance corporate investment spending. The supply of saving function would be identical to the demand for investment function. In such a world what forces would determine the profit rate and limit the level of net investment? Irrespective of the volume of investment chosen, there would never be a problem of financing or of insufficiency of aggregate demand. An increase in the share of investment would require an increase in retained earnings and, assuming the payout ratio is constant, a rise in profits and so in the ratio of prices to costs. Increased investment spending thus necessarily involves lower consumption spending and a lower level of real wages w/P.

If wages are regarded as determined by a struggle over distributive shares between workers and capitalists, Robinson has argued that there is some minimum level of real wages at which money wages tend to rise rapidly as workers are determined and able to resist further deterioration in their real wages. This "inflation barrier" sets a limit on the ability of firms to increase profit margins to finance a higher level of investment and so limits the investment income ratio and the rate of accumulation. The Knightian argument is that in a world of uncertainty investment would never be carried beyond the point where the expected rate of profit on new investment was sufficiently high to compensate for the irreducible degree of uncertainty involved in business enterprise. The degree of risk aversion on the part of firms thus sets a floor to the required rate of return to investment. Competition will also set a limit to the rate of investment in such a world. Firms can increase investment only by increasing retained earnings and, after payouts have been reduced to their minimum value, by raising the ratio of prices to costs. As a result they will lose business to firms that are content to grow more slowly and therefore can charge lower price markups over cost, since such firms do not require as large a volume of retained earnings.

---

[11] The expected rate of profit on new investment must be clearly distinguished from the observed rate of profit on capital P/K. Profits received on existing assets consist of a series of rents and quasi rents. With technological change the quasi rents earned on older capital goods decline with age until they are scrapped. The value of the existing capital stock cannot in general be determined independently of the profit rate. As a result the observed ratio P/K is of little analytical meaning outside of a golden age. As Mario Nuti states, "The ideological role of the value of capital is that of breaking the actual direct link between the time pattern of labor inputs and the time pattern of output in which any technology can be resolved, and establishing instead a relationship between current output and current labor" (p. 54).

The present argument suggests an additional mechanism which operates to limit the rate of investment and set a floor to the rate of profit. As shown in equation (13) the long-run rate of return on corporate stock (when $i=0$ and $dv=0$) cannot fall below the dividend yield plus the growth rate of corporate earnings (assets). At the limit as share prices become indefinitely large the dividend yield approaches zero, and the return on equities approaches the growth rate. But this return on equities operates to govern the rate of profit so long as firms are concerned about the price of their shares. As shown above (equation (13′)), when all firms operate to maximize share prices so that $v=1$, the rate of profit (P/K) will be equal to the discount rate r.

In capitalist economies the return on property claims cannot be reduced below the growth rate of the future stream of income to which the owner of the claim is entitled. As returns fall towards this level the market values of property claims, as the discounted value of future income streams, become indefinitely large, as does the ratio of comprehensive income to output.[12] Thus even in a world in which by assumption all property income represents economic rent, and rates of return are totally functionless from the viewpoint of inducing saving, it would not be possible to eliminate property income, nor to reduce the return on wealth ownership below the growth rate, even though no income return is required to induce wealth owners to forego present consumption and bribe them to accumulate.

A final implication of the analysis is that while the profit rate and the rate of return on equities indeed rests on three legs, only one of these, the productivity of new investment, was recognized by Böhm-Bawerk. The other two are the growth rate of the economy and the proportion of property income which is saved and invested. The profit rate must be sufficiently high to finance the level of investment consistent with the capital-labor ratio and rate of growth of effective labor. The higher the proportion of profits saved (s_B, s_G, s_P, s_L), the lower the profit rate. But the aggregate saving ratio depends more on institutional factors, in particular wealth distribution, than on time preference.

In a modern market economy the volume of household saving is closely dependent on the volume of business investment, depending on the degree of wealth concentration. While lower and middle income individuals may adjust their present and future consumption plans in response to a change in the rate of return on wealth, they are not "representative" savers, since their margin is not significant in governing aggregate saving behavior.[13] Equity returns and profit rates would be positive in growing economies even if the reservation price of savers were zero and all property income represented pure economic rent.[14] To conclude that the rate of profit on capital and the rate of return on wealth is determined by individual time preference represents a colossal inversion of causality.

---

[12] As noted above in a growth context the reduction of property returns towards the growth rate of the economy, and not to zero, is sufficient for the long-run euthanasia of the rentier. Rentier saving ratios would then have to approach 100 percent in order to prevent their relative share of total wealth from declining to zero in the long run.

It is concentration of property ownership in addition to the capitalist ethic that make capitalism as a system such a powerful engine of accumulation. Paradoxically, by ensuring that a large proportion of property income is saved, concentration of wealth serves in part to condone the institution of private property itself. In Keynes' famous double bluff passage he observed that capitalists, though they do no work, "were allowed to call the best part of the cake theirs, and were theoretically free to consume it, on the tacit underlying condition that they consumed very little of it in practice." Or as another famous critic of capitalism has put it, "Accumulate! Accumulate! That is the law of Moses and the Prophets." But one price is the very considerable inequality of income and opportunity, which could be reduced by the differential taxation of property income, or by the collective ownership of property claims to society's real wealth. This policy conclusion is reinforced by the first bluff, that it is the abstention of workers and not of capitalists that provides the surplus for accumulation.

[13] For an early expression of the position that the rate of interest is not governed by time preference, see Frank Knight. He argued that "the thing desired is possession," and not future consumption, that "the motivation is not economic in the ordinary sense but sociological" (p. 286). He detailed a number of reasons why net saving was carried beyond the individual lifetime of members of the social class from which capital accumulations actually come.

[14] The fact that asset accumulation continues in the present inflation, when real returns on fixed income financial assets are negative, is an indication of the interest inelasticity of the supply of saving, at least in the short run, and the extent of economic rent in property income.

Constraints on Government Investment Opportunities and the Choice of Discount Rate

By David F. Bradford*

In his well-known paper on the choice of discount rate for public investment decisions, William Baumol noted the apparent impossibility of reconciling the arguments in favor of using a pure time preference rate with those in favor of using the marginal rate of return to private investment, the "opportunity cost" of funds. On the one hand it would seem there is a clear opportunity for welfare gain in undertaking an investment with rate of return in excess of a social time preference rate, however determined. On the other hand, it would clearly be possible to do even better by leaving the resources in the private sector if the rate of return on private investment exceeded the return on the government project.

The way out of this dilemma which had already been expressed by Kenneth Arrow (and was subsequently elaborated upon by Arrow and Mordecai Kurz), is to make explicit the optimization problem, including its constraints, confronting the government. Assuming there is a solution to this optimization problem, there is, correspondingly, a "correct" discount rate (or, more generally, term structure of discount rates) applicable to the project.

In this paper I explore the practical relevance of one of the more remarkable conclusions of Arrow's paper, which can be roughly stated as follows: if capital market imperfection takes the form of a fixed marginal propensity to save out of private income (independent of the rate of return), the optimal government investment policy in the long run is to invest to the point where the marginal rate of return on government capital equals the marginal rate of social time preference (whether or not derived from individuals' rates of time preference), *regardless of the rate of return on private capital.*

Whereas Arrow considered the problem of optimally setting the level of a homogeneous public capital stock, I address the question of whether a project producing certain output flows should be accepted or rejected, where the decision is assumed not to affect any of the relevant marginal rates of transformation or substitution, which are regarded as constant. It proves possible to use a very simple line of argument to show why and under what conditions the analogue of the Arrow proposition holds and to indicate how modification of the conditions of the problem change the public investment criterion. The policy of discounting according to a pure time preference rate turns out to be surprisingly robust to plausible variations in the parameters describing the underlying (second best) optimization problem.

All of the results, it should be stressed, describe second best policies. That is, they depend upon the existence of constraints on government investment opportunities which are "artificial" in the context of the economic model, although possibly neither unrealistic nor unreasonable as political devices. These are the constraints which restrict government investment to certain classes of activities. Because of such restrictions, apparently attractive returns in the private sector may not represent opportunity costs for the government at all, or at least not directly. When the private investment opportunities are not also government investment opportunities, private rates of return become irrelevant to government choices. This is the key to the argument.[1]

---

* Princeton University. An earlier version of this paper appeared as Research Memorandum No. 67, Institute for Advanced Studies, Vienna, May 1972. My debt to the work of K. J. Arrow and M. Kurz is great, and through them to the work of S. A. Marglin and O. Eckstein. I would like to acknowledge and recommend as well a paper by Martin Feldstein which uses a similar approach, although I choose to stress different aspects of the problem.

Section I contains the basic model and the most important conclusions. Briefly, the argument focuses on the comparison between the amount of reduction in private capital formation caused by the shift of one dollar into the public sector and the increase in private capital formation induced by an increase of one dollar in the value of government services. If capital market imperfection causes the value of the extra capital obtainable by a reduction of one dollar in consumption to exceed one dollar (shadow price of capital in excess of unity), a given government investment becomes the more attractive the smaller the private investment-discouraging effect of its financing and the greater the private investment-encouraging effect of its output flow. For the special case in which these private investment effects are at the same rate per dollar, and assuming the shadow price of capital to be constant, a public investment with rate of return in excess of the rate of time preference should be undertaken. This would, under the assumption of capital market imperfection, imply government takeover of private investment, a rather radical result ruled out by the assumed limitation of the government's sphere of operation. More modestly, the result implies (for the noted special case of the parameters) that the government should use the rate of time preference in discounting its available investment opportunities.

The remaining sections are principally concerned with amplifications and extensions required to move the analysis toward practical applicability. In Section II, I discuss the procedure for calculating the shadow price of capital and present plausible illustrative magnitudes. In Section III the model is extended to recognize many different private investment sectors, a refinement principally motivated by the view that a corporation income tax leads to different (social) rates of return on different forms of private capital. In Section IV the case of multiperiod projects is considered. The most important contribution of this exercise is to emphasize that the basic discount rate in the government's calculations is the time preference rate. The private-investment parameters here determine factors by which costs or benefits are to be inflated or deflated. While for the case of one-period investments these effects can be equivalently expressed as variations in the discount factor, for multiperiod investments this is not so. For investments of any significant duration the distinction is crucial. This point is used in Section V in which, after commenting on the prospects for detailed application of the model, I return to the thesis that discounting at a pure time preference rate is a defensible rule of thumb for government choices.

Some final introductory remarks: in this paper the features of the investment problem arising from uncertainty are given no explicit attention, even though these are presumably relevant to explaining the simultaneous existence of different rates of return. For our purposes here it is sufficient to view all rates of return and time preference as certain. It is implicitly assumed, furthermore, that it makes sense for the government to base its investment decisions on preferences about *aggregate* consumption flows. That is, it is assumed that either the intratime period income distributional effects of investment choices are unimportant, or mechanisms are at hand to adjust the income distribution to any desired extent within each time period.

---

[1] In a previous paper, I showed how constraints on government actions affected choice criteria in the presence of multiple rates of time preference contemporaneously held by the members of society. In this paper I am concerned with a different problem. The source of the trouble here is multiple rates of return on investment. It arises even if all members of society (or some designated welfare evaluator) are in agreement about the appropriate rate of substitution among consumption in different time periods.

I. The Basic Argument in a Simple Model

The essence of the analysis is adequately expressed in context of a simple model, in which it is assumed there is only one kind of private capital and all the yield from an investment takes place in the immediately following period. In such a model, in fact, one does not need to make a distinction between capital stock and investment flow. In each period the whole capital stock is up for grabs, and may be consumed or invested.

Let c_t stand for the level of aggregate consumption in period t. It is assumed that the government acts according to a preference structure over time streams of consumption. For our purposes it is not necessary to establish the basis—for example, the time preferences of the households at each moment—on which the government determines the relative desirability or "social value" of alternative consumption paths. From such a structure emerges naturally a sequence of "social rates of time preference" i_t, corresponding to each sequence of consumption levels c_t: $1+i_t$ is simply the social marginal rate of substitution of c_{t+1} for c_t.

Assume that investment in private sector capital has a marginal one-period rate of return r_t in period t. That is, $1 invested in period t increases the total number of dollars available in period t+1 by $(1+r_t)$ dollars. An increase in the private capital stock at any time may be expected to have an impact on the entire future consumption stream, since some of the proceeds are likely to be consumed in the next period, while a further part will be reinvested to affect consumption still farther in the future. Obviously, it may be a difficult task to identify the "perturbation" of the consumption stream resulting from a $1 change in private capital at time t, but let us imagine that this has been done, and let v_t stand for the discounted value of the sequence of consumption changes, where the discount factors are derived in the usual manner from the sequence i_t of social rates of time preference.

To clarify what v_t is, imagine that a unit of time t capital drops like manna from heaven, affecting the whole stream of consumption starting at time t+1. In this new consumption stream, by how much at most could one reduce the amount of consumption in period t, and still have a consumption stream as valuable (according to the government preferences) as the original, pre-manna, consumption stream? The answer is v_t, and in this sense, v_t is the social value of a unit of private capital at time t. Note carefully that v_t is measured in units of time t consumption. Because of their analytical function, I shall adopt Feldstein's practice of calling the v_t simply the "shadow prices" of private capital.

Now let us suppose that the government is contemplating undertaking an investment in period t which has a rate of return ρ_t. That is, $1 invested in the government opportunity in question will make available an increase of $(1+\rho_t)$ dollars in period t+1. The question now is, under what conditions would an incremental unit of the government investment lead to a better time stream of consumption (from the social point of view). The answer is made difficult by the fact that, through its influence on private capital formation in periods t and t+1, the government investment decision affects the entire future consumption sequence. However, having equipped ourselves with the sequence of social values of capital v_t, we are in a position to evaluate these indirect effects more easily.

Let a_t be the amount by which private capital formation is decreased as a result of the financing of an additional dollar of government investment. Under the usual full employment assumption, $(1-a_t)$ is the corresponding loss in period t consumption.[2] For some forms of finance we would expect to find $a_t=s_t$, the marginal propensity to save out of disposable income, although clearly we shall wish to associate different a_t with different techniques of financing government investment.[3]

Let α_t be the amount by which private capital in period t is increased as a consequence of an increase of $1 in the output of the government sector in period t. Whereas a_t shows the *reduction* in private capital formation caused by an increase of one unit in financing, α_t shows the *increase* in private capital formation caused by a unit flow in the other direction in the form of government services, measured in dollars. For the case in which revenue is raised by direct taxation of consumer citizens and in which the implicit income from the government project is treated exactly like ordinary, after-tax income, $a_t=\alpha_t=s_t$. (This is the Arrow-Kurz assumption.) However, we must admit the possibility that these three parameters differ.

TABLE 1—THE EFFECT OF UNDERTAKING AN ADDITIONAL ONE DOLLAR OF GOVERNMENT INVESTMENT AT TIME t

	Period t	Period t+1
Change in Consumption	$-(1-a_t)$	$(1+\rho_t)(1-\alpha_{t+1})$
Change in Private Capital Formation	$-a_t$	$(1+\rho_t)\alpha_{t+1}$

It is now a simple matter to tote up the various effects of raising an additional dollar in period t to finance government investment. Table 1 shows the impact on consumption and capital formation in periods t and t+1. We know that the value in period t consumption units of $1 of private investment is v_t. Hence the effective loss in period t consumption as a result of the government investment is $1-a_t+a_tv_t$ dollars. Similarly, the value of the increase in consumption and private investment in period t+1, expressed in period t+1 consumption units, is $(1+\rho_t)\cdot(1-\alpha_{t+1}+\alpha_{t+1}v_{t+1})$. Discounting the effective t+1 consumption increase to period t at the social rate of time preference i_t, we obtain an expression for the net gain from the whole transaction:

$$(1)\quad -(1-a_t+a_tv_t)+\left(\frac{1+\rho_t}{1+i_t}\right)(1-\alpha_{t+1}+\alpha_{t+1}v_{t+1})$$

By definition of i_t, we shall attain a more valued consumption stream if we undertake government investment so long as expression (1) is positive, a condition expressed by inequality (2),

$$(2)\quad \frac{1+\rho_t}{1+i_t}\geq\frac{1+a_t(v_t-1)}{1+\alpha_{t+1}(v_{t+1}-1)}$$

which determines by how much, if at all, the rate of return ρ on the government investment must exceed the social time preference rate i in order to make the investment worthwhile.

---

[2] It would not be difficult to recognize the possibility of underemployed resources, and hence to include explicitly separate parameters for the investment and consumption effects here, but it would clutter up the argument.

[3] The use of the general approach taken here to analyze the choice of financing method is the principal subject in Feldstein's paper.

A. *Some Important Special Cases*

It is useful to consider the implications of condition (2) as a government investment criterion in special cases corresponding to various assumptions about the coefficients a_t, α_t, and v_t. The effect of a rising or falling shadow price of private capital works in the same direction under all meaningful assumptions about the other coefficients. A glance at conditions (2) will show that increasing v_{t+1}, holding v_t constant, tends to raise the denominator on the right-hand side and hence to reduce the critical rate at which ρ_t becomes an acceptable rate of return on the government project. The effect of decreasing v_{t+1}, holding v_t constant, is in the opposite direction. We shall interpret this result below. For the moment we simply note that to consider the consequences of varying the other parameters it is sufficient to look at the cases for which $v_t = v$, a constant. There are four extreme cases of special interest.

Case 1: $a_t = \alpha_{t+1}$. An additional dollar's worth of output from a government project causes the same increment in private capital formation as does a reduction of $1 in the amount raised through the financing instrument corresponding to which a_t is defined. This case is the rather remarkable one distinguished in the introduction. Substituting into condition (2) we see that the acceptance condition for the public investment becomes

$$\frac{1 + \rho_t}{1 + i_t} \geq \frac{1 + a_t(v - 1)}{1 + a_t(v - 1)} = 1 \tag{3}$$

This says that *government investments should be accepted as long as the marginal rate of return exceeds the time preference rate.* The surprising aspect of this case is that the rate of return in the private sector, sometimes called *the* opportunity cost of funds, does not enter the calculation at all. The reason is that by our assumption that $\alpha_{t+1} = a_t$, we have assured that for every dollar of reduced investment in period t, the government project puts back $(1+\rho_t)$ dollars of increased investment in period t+1. The issue then is, how much must we increase investment in period t+1 to compensate for a loss of one unit in period t. Since $v_t = v_{t+1}$, the answer is $(1+i_t)$ dollars.

Case 2: $a_t = 1$, $\alpha_{t+1} = 0$. Under these assumptions, which are often made, at least implicitly, *all* of the resources for the project come from investment and the output induces no increase in private investment. Here the usual argument is that a project is acceptable if and only if it has a rate of return greater than or equal to that in the private sector. According to the present analysis this is generally not strong enough. Condition (2) becomes

$$\frac{1 + \rho_t}{1 + i_t} \geq v_t \tag{3'}$$

Under the conditions in which v_t, i_t, r_t, and s_t (which we have called the marginal propensity to save) are all constant, we shall see in Section II that $v_t > \gamma \equiv (1+r)/(1+i)$, indicating that the government project must have a return rate in excess of r to pass muster under the assumptions of Case 2. The reason for this is simply that the government project does not generate the favorable repercussions on future capital formation which the private investment does.

Case 3: $a_t = 0$, $\alpha_{t+1} = 1$. In this case all resources for the project come from consumption and all yield is converted into private capital. Condition (2) becomes

$$\frac{1+\rho_t}{1+i_t} \geq \frac{1}{v_t} \tag{3''}$$

For obvious reasons this case would allow as desirable projects for which rate of return is actually below the time preference rate, and a fortiori below the rate of return in the private sector.

Case 4: A Two-Period World. Many analyses of the public investment problem have employed a two-period model, with the second period taken to represent "the future." For some purposes this is a satisfactory procedure, but in the present context it amounts to a very special case of our general analysis, and one with no particular claim to policy relevance. Since in a two-period world it makes no sense to speak of investment in the second period, we have $\alpha_{t+1}=0$. The other special aspect of the two-period world is the ease with which one can calculate the value of v_t. For with no capital formation in period t+1, a unit increment to period t capital must generate $(1+r_t)$ extra units of consumption. The period t consumption value of this, v_t, is $(1+r_t)/(1+i_t)$. With these special assumptions, condition (2) becomes

$$\rho_t \geq (1-a_t)i_t + a_t r_t \tag{3'''}$$

i.e., the condition that the yield on the government investment must exceed a weighted average of the rate of time preference and the private investment yield, the weights being the proportions in which the resources are taken out of consumption and private investment, respectively. Note the very special assumptions underlying this conclusion: no future capital formation consequences of increments in *either* government or private investment.[4]

B. *Summing Up the Analysis of the Simple Model*

The essential conclusions to be drawn from the simple model are obtained from an examination of condition (2). It says that the required yield on a government investment project exceeds the rate of time preference if the dollar reduction in current private investment per dollar withdrawn to finance the government project exceeds the dollar increase in private investment per dollar of value of the project's output $(a>\alpha)$ (assuming $v>1$). The required yield on the government project falls below the time preference rate if the inequality is reversed. The extent of the divergence in each case depends upon v; the larger is v, the larger is the divergence.

As has been pointed out, a tendency for v to grow with time favors government investment, *ceteris paribus*. The reason for this is that the government investment serves in part to *shift private investment toward the future*. The more rapidly v is rising, the less future private investment do we need to offset the loss of any given amount of current investment. By the same line of reasoning, a tendency for v to fall with time raises the minimum acceptable rate of return on government projects.

Although there remains much to be said in the following sections about how one might estimate the values of the various parameters, especially v_t, and about how the simple model can be generalized, the most important theoretical points have already been established. For the analysis has shown how it is possible to reach a definite resolution of the difficulty described by Baumol and referred to in the introductory section. The solution generally lies, interestingly enough, not on either horn of the dilemma, time preference or private productivity discounting, and may not even lie between the two apparent extremes.

---

[4] Peter Diamond derived this same condition, at the same time stressing the limitations of a two-period model. Agnar Sandmo and Jacques Drèze also obtain this formula in a two-period model.

The second best character of these conclusions, resulting from constraints on the government's investment opportunities, must be strongly stressed. How, it will be asked, can it possibly make sense for the government to invest in a project with a yield of 5 percent when there are projects available in the private sector yielding 10 percent? The answer is that this can make sense ***only if the private sector investment is not also an investment opportunity for the government.*** In our model the government participates in the private sector investment opportunity only indirectly, via its choice of public sector investments (and via its choice of financing instruments). By taking into account in advance the response of private sector investment to government actions it is possible to evaluate the entire stream of consequences of a particular choice. Because of the limited set of investment opportunities considered appropriate for the government, and because of the divergence between private and social value of private capital, it can follow that it is better to undertake the 5 percent project than not to undertake it, which is the real choice. The apparent 10 percent opportunity cost is no such thing, since the investment in question does not represent an "opportunity" for the government at all.

II. Calculating the Shadow Prices

By keeping track of the string of consumption consequences of adding a unit of private capital to the system at time t, and discounting them to time t, we arrive at an expression for v_t:

$$(4)\quad v_t = \gamma_t\left[(1 - s_{t+1}) + \sum_{k=2}^{\infty}(1 - s_{t+k})\prod_{j=1}^{k-1}\gamma_{t+j}s_{t+j}\right]$$

where

$$(5)\qquad \gamma_{t+j} = \frac{1 + r_{t+j}}{1 + i_{t+j}}$$

For the special case of $\gamma_{t+j}=\gamma$, and $s_{t+j}=s$, constants, (4) becomes

$$(6)\qquad v_t = (1 - s)\gamma\sum_{k=0}^{\infty}(s\gamma)^k$$

or

$$(7)\qquad v_t = \frac{(1 - s)\gamma}{1 - s\gamma}$$

assuming $s\gamma<1$, as necessary for convergence.

Since in most cases of interest $r>i$, and hence $\gamma>1$, we find $v_t>1$; an extra dollar invested at time zero generates a stream of consumption changes worth more than \$1. Note further that generally $v_t>\gamma=(1+r)/(1+i)$. We may check that for the special case $i=r$, $v_t=1$.

A. *A Difference Equation Formulation*

Expression (4) can be regarded as a difference equation in the shadow price of private capital, which can be derived directly. An increment of investment at time t generates extra consumption at t+1 equal to $(1+r_t)(1-s_{t+1})$, and extra investment equal to $(1+r_t)s_{t+1}$. The latter is equivalent to $(1+r_t)s_{t+1}v_{t+1}$ units of period t+1 consumption, by definition of v_t. Finally, since c_{t+1} units of t+1 consumption are equivalent in social value to $c_{t+1}/(1+i_t)$ units of time t consumption, by definition of i_t, we conclude that \$1 extra invested at time t has a value

$$(8)\quad v_t = \frac{(1 + r_t)(1 - s_{t+1}) + (1 + r_t)s_{t+1}v_{t+1}}{1 + i_t} = (1 - s_{t+1} + s_{t+1}v_{t+1})\gamma_t$$

For the constant coefficient case, $\gamma_t=\gamma$ and $s_t=s$, (8) has steady-state solution $v_t=(1-s)\gamma/1-s\gamma$ to which convergence is

Table 2—The Shadow Price of Private Capital Under a Range of Assumptions About Parameter Values

	$s=.10$			$s=.20$			$s=.30$		
r	.05	.10	.15	.05	.10	.15	.05	.10	.15
i									
.02	1.03	1.09	1.14	1.04	1.10	1.16	1.04	1.12	1.19
.05	1.00	1.05	1.11	1.00	1.06	1.12	1.00	1.07	1.14
.08	.97	1.02	1.07	.97	1.02	1.08	.96	1.03	1.10

assured if $s\gamma<1$. If the system has always had these constant coefficients, the shadow price must be constant at the steady-state value. Note that one can use (8) to compute v_t under more general conditions by making assumptions, for example, about its rate of growth.

B. *Illustrative Numerical Values of the Shadow Price of Capital*

The simple formulation which results from assuming the various coefficients to be constant makes it easy to get some feel for the magnitudes which might be involved in application. The cells of Table 2 contain the shadow prices of private capital implied by various combinations of values of the three parameters, s, i, and r, chosen to bracket the empirically plausible range. The range of v is from 0.96 ($s=.20$, $r=.05$, $i=.08$) to 1.19 ($s=.30$, $r=.15$, $i=.02$).

III. Generalizing to Many Private Investment Sectors

There are a number of ways in which the simple model can be generalized, and it would probably be of little use at this point to produce a catalogue of possibilities. However, in view of the previous treatment of this topic by Baumol and others, we should consider explicitly the possibility of more than one private sector. It is customary by now to think of private investment as being of two types, corporate and noncorporate, where decisions in the former sector are influenced by the corporation income tax. Hence, we start by considering a two-private-sector model.

Let a_t^1, then, represent the fraction of an incremental dollar raised to finance government activities which comes out of noncorporate capital formation. Let a_t^2 be the corresponding value for corporate capital. Define α_t^1 and α_t^2 in the analogous manner, indicating the amounts of capital formation in sectors 1 and 2 induced by a $1 increase in government output in period t. Let v_t^1 and v_t^2 be the appropriate shadow prices of capital in the two sectors, given their respective rates of return, r_t^1 and r_t^2. Table 3 shows the effect of undertaking an additional $1 of government investment at time t in this model world. By a line of reasoning parallel to that leading to condition (2), the criterion for acceptance of the government investment can be expressed as

$$\text{(9)}\quad \frac{1+\rho_t}{1+i_t} \geq \frac{1+a_t^1(v_t^1-1)+a_t^2(v_t^2-1)}{1+\alpha_{t+1}^1(v_{t+1}^1-1)+\alpha_{t+1}^2(v_{t+1}^2-1)}$$

The interpretation of condition (9) runs along the same lines as our previous interpretation of condition (2), and presents no special difficulties. Of particular interest is the case $a_t^1=\alpha_{t+1}^1$, $a_t^2=\alpha_{t+1}^2$ in which dollars taken out of the private sector by the financing methods and implicit dollars put

TABLE 3—THE EFFECT OF AN ADDITIONAL ONE DOLLAR OF GOVERNMENT INVESTMENT WHEN THERE ARE TWO PRIVATE INVESTMENT SECTORS

	Period	
	t	t+1
Change in Consumption	$-(1-a_t^1-a_t^2)$	$(1+\rho_t)(1-\alpha_{t+1}^1-\alpha_{t+1}^2)$
Change in Noncorporate Capital Formation	$-a_t^1$	$(1+\rho_t)\alpha_{t+1}^1$
Change in Corporate Capital Formation	$-a_t^2$	$(1+\rho_t)\alpha_{t+1}^2$

into the private sector in the form of yield on the government investment are divided among consumption and investment in the two sectors in the same proportions. In this case, if the shadow prices of capital are constant, condition (9) becomes simply

$$\frac{1+\rho_t}{1+i_t} \geq 1$$

The government project's yield rate need be only as high as the social rate of time preference.

A. *Calculating the Two Shadow Prices*

If we assume constant propensities to save/invest, constant rates of return, constant social rate of time preference, and constant values of the two shadow prices, v^1 and v^2, we can calculate the latter without particular difficulty. Again, by a derivation analogous to that leading to equation (8), we conclude that v^1 and v^2 must satisfy

$$(10)\quad v^1 = \frac{1+r^1}{1+i}\left[1 + s^1(v^1-1) + s^2(v^2-1)\right]$$

$$v^2 = \frac{1+r^2}{1+i}\left[1 + s^1(v^1-1) + s^2(v^2-1)\right]$$

Define γ^1 and γ^2, analogous to γ in the one-sector analysis. Then, assuming $1-\gamma^1 s^1 - \gamma^2 s^2 \neq 0$, (10) implies that the shadow prices are proportional to γ^1 and γ^2:

$$(11)\quad \begin{bmatrix} v^1 \\ v^2 \end{bmatrix} = \left(\frac{1 - s^1 - s^2}{1 - \gamma^1 s^1 - \gamma^2 s^2}\right)\begin{bmatrix} \gamma^1 \\ \gamma^2 \end{bmatrix}.$$

Under the assumption sometimes made that the social rate of time preference is equal to the private rate of time preference and that this is in turn equal to the rate of return in the noncorporate sector, $r_t^1 = i_t$, i.e., $\gamma^1 = 1$. Notice that because some of the throwoff from each sector is invested in the other, *even in this case* generally $v^1 > 1$.

If we increase the number of private investment sectors beyond two, the government investment test changes from (9) to

$$(12)\quad \frac{1+\rho_t}{1+i_t} \geq \frac{1 + \sum_{j=1}^{m} a_t^j (v_t^j - 1)}{1 + \sum_{j=1}^{m} \alpha_{t+1}^j (v_{t+1}^j - 1)}$$

where m is the number of sectors. Again, note the simple and symmetric way in which the various private sectors enter criterion (12). For the case in which the various coefficients and the shadow prices are constant over time we can calculate them in the manner of expression (11) from

$$(13)\quad \begin{bmatrix} v^1 \\ v^2 \\ \cdot \\ \cdot \\ v^m \end{bmatrix} = \left(\frac{1 - \sum_{j=1}^{m} s^j}{1 - \sum_{j=1}^{m} \gamma^j s^j}\right)\begin{bmatrix} \gamma^1 \\ \gamma^2 \\ \cdot \\ \cdot \\ \gamma^m \end{bmatrix}$$

where $\gamma^j \equiv (1+r^j)/(1+i)$. Here, as in the two-sector example, shadow prices v^i are all in the *same proportion* to (and in the normal case larger than) the coefficients γ^i, which represent the social-time-preference discounted value of marginal returns in sector i.

IV. Treatment of Multiperiod Returns

Thus far the analysis has been carried on as though the government were always in a position of choosing an investment requiring inputs of \$1 in period t and producing its entire output $\$(1+\rho_t)$ in period t+1. This permitted us to express the investment criterion in terms of the relationship between a well-defined rate of return (essentially, the one-period internal rate of return) and corresponding rate of time preference. However, it is a relatively simple matter to deal with more complex patterns of returns.

We capture most of the interesting aspects of this generalization by supposing that our typical government project can be described by two time sequences of numbers: b_t denoting the current dollar (consumption equivalent) value of the government service provided in period t, and e_t denoting the additional resources which must be raised in period t to carry out the project. Note that in any given period either b_t or e_t or both *may be negative.* A negative value of b_t corresponds to costs such as environmental damage caused by the project. A negative value of e_t may result when the project yields a cash return—for example, its output is sold on the market—which may be applied toward a reduction in taxes in that period. Negative values for these variables may occur in another way as well. Our analysis applies equally to investment and disinvestment. *Not* undertaking a project is itself a project; if project A is described by $\{b_t, e_t\}$, the project "not undertaking A" is described by $\{-b_t, -e_t\}$.[5]

Things will be simplified somewhat if we define shadow prices for benefits and revenues as follows:

$$\beta_t = 1 + \sum_{j=1}^{m} \alpha_t^j (v_t^j - 1) \tag{14}$$

$$\epsilon_t = 1 + \sum_{j=1}^{m} a_t^j (v_t^j - 1)$$

where the sums in (14) are taken over all of the private sector investment possibilities distinguished by the model. The term β_t is the social value (in dollars of time t consumption) of a dollar's worth of benefits when account is taken of the induced effects on private capital formation. Similarly, ϵ_t is the social value of the lost consumption and capital formation resulting from raising an additional dollar of finance.

In period t the government project produces b_t dollars in benefits, worth $b_t\beta_t$ dollars in period t consumption when the influence on private capital formation is taken into account. The project requires that e_t dollars in revenue be raised at a cost equivalent to $e_t\epsilon_t$ dollars of period t consumption when the influence on private capital formation is taken into account. For convenience let the point of reference be called t=0. The net effect is $b_t\beta_t - e_t\epsilon_t$ which is equivalent to $\delta_t(b_t\beta_t - e_t\epsilon_t)$ units of period 0 consumption, where δ_t is the *discount factor* derived from the social time preference term structure in the familiar manner. The project is worthwhile if

$$\sum_{t=0}^{T} \delta_t(b_t\beta_t - e_t\epsilon_t) \geq 0 \tag{15}$$

where the project has its last direct payoff or resource requirement in period T. It is easily checked that condition (15) gives us back the criterion for one-period investments (12) for which $b_{t+1}=1$, $b_\tau=0$ otherwise; $e_t=1$, $e_\tau=0$ otherwise.

---

[5] Note that we are here assuming only one form of benefits and only one form of finance. More generally, we could describe a project by a sequence of vectors $(b_t^1, b_t^2, \ldots, b_t^s, e_t^1, \ldots, e_t^r)$, where b_t^j = dollars worth of benefits of the jth type (of s types in all) in period t, and e_t^k = dollars required from finance source k (of r sources, e.g., sales tax, debt issue, etc.) in period t.

For the case in which an additional dollar of benefits is divided among consumption and the different sorts of private investment in the same way every year and the shadow prices of the different sorts of private capital are constant, $\beta_t=\beta$, a constant. If an additional dollar of financing comes out of consumption and the different sorts of investment in the same proportions every year and if the shadow prices of capital are constant, then $\epsilon_t=\epsilon$, a constant. Then (15) becomes

$$\sum_{t=0}^{T} \delta_t \left(b_t - \frac{\epsilon}{\beta} e_t\right) \geq 0 \tag{16}$$

investments should be evaluated by discounting at the social time preference rate, with government cash flows inflated by a factor ϵ/β. For the one-sector case we have seen a plausible *extreme* range for this weighting factor is $1/v \leq \epsilon/\beta \leq v$, with $\epsilon/\beta=1/v$ for $a_t=0$, $\alpha_t=1$, and $\epsilon/\beta=v$ for $a_t=1$, $\alpha_t=0$. When $\alpha_t=a_t=$ constant (changes in financing have the same impact on private investment as changes in value of government services), $\epsilon/\beta=1$, the criterion becomes simply to discount all flows, unweighted, at the social rate of time preference.

V. Concluding Remarks

In a sense, condition (15) with its associated definitions is the general solution to the public investment problem and hence the general conclusion of this analysis. The next step required is to put empirical flesh on the theoretical structure in the form of actual estimates of the various coefficients of condition (15). However, for various reasons, one should not be overoptimistic about obtaining a set of coefficients which can be applied to any government investment problem to lead to a correct choice.

First, the precise financing technique providing the source of funds for any government project is often unclear or not even well defined, and these sources vary from project to project. Do the funds to pay for a subsidy to the merchant marine come from corporation income taxes? Personal income taxes? Changes in federal debt? A correct answer would not even be assured if expenditure laws specified the source of finance. For example, federal highway programs are nominally financed by gasoline taxes, and this may be the end of the story. However, it is also possible that gasoline taxes would be about what they are anyway. An increase in highway expenditures in this case forces some other program to find its financing in another revenue device, say, the personal income tax. Then the source of finance for the highway expenditure for our purposes is in fact the personal income tax. Furthermore, the source of finance for a project may well be funds which would otherwise have financed another government activity. In this case, then, the dollars for the project in question "cost" the foregone benefits from the alternative activity. We need not labor further the extreme difficulty of establishing the financing source.

Second, knowing the financing source, we must establish how much of an incremental dollar from that source derives from consumption, how much from various forms of private capital formation (and, we might add, how much from unemployed resources). It is not sufficient to know simply the nominal payers of a tax, as it is the ultimate payers whose savings are affected.

Third, on the output side, matters are not much better. Assuming, as we have been, that one can reasonably estimate dollar values of the services from the government project, determining the influence of these flows on private investment is likely to be extremely difficult. Some headway may be made by examining the character of the flow involved. Is it more like consumption or more like savings? If the government undertakes to provide medical care for the aged, presumably this reduces the incentive for citizens to accumulate a reserve against this possibility. We might expect, then, that providing an additional dollar's worth of this insurance protection will lead individuals to reduce their private savings by about a dollar and to increase consumption by a like amount. At the other extreme, benefits from public parks may be effectively pure substitutes for private consumption. A family receiving these benefits reduces its expenditures on film and baseball game attendance, and increases its savings accordingly.

Note, though, that what a service looks like may tell only part of the story. The park example illustrates this. While it is true that the recreational services are of a nature which we would usually label "consumption," there is no guarantee that these services replace other consumption. They may be additive; they may even induce a reduction in labor supply and a net decrease in private saving ($\alpha<0$).

In view of these very serious obstacles to a precise implementation of (15), we would do well to consider what rules of thumb are likely to make sense and the circumstances in which they are likely to lead us astray. The argument in this paper suggests the simple principle: *Maximize present value of net dollar flows (including dollar equivalents of nonmarketed effects), discounting at the social rate of time preference.* As we have seen, assuming v_t, α_t, and a_t constants, reasonable extremes of condition (15) are given by the cases of (16) corresponding to $\beta=v$, $\epsilon=1$ and $\beta=1$, $\epsilon=v$. In the latter case, in which all financing comes out of investment and all benefits increase consumption, we should multiply financing changes by a factor v before calculating net benefits. If we nevertheless use our rule of thumb we shall, of course, undertake some socially unprofitable projects. For a project just barely worthwhile according to the rule so that $\Sigma\delta_t b_t=\Sigma\delta_t e_t$, undertaking the project will lead to a net loss equal to $(v-1)\ \Sigma\delta_t e_t$. At the other extreme, where all yield from the project leads to an equivalent value increase in private investment and all finance for the project derives from consumption ($\beta=v$, $\epsilon=1$), the rule of thumb is too conservative. The apparently barely worthwhile project will actually generate a net profit of $(v-1) \cdot\Sigma\delta_t e_t$.

Just how serious are these extreme errors? They are obviously sensitive to the value of v, the shadow price of private capital. This is an empirical matter but, forced to make a guess, and looking at Table 2, I would think $1.10 to be on the high side and $1.05 to be reasonable. If the *extreme* risks of error run the range from -5 percent to $+5$ percent of the value of the resources involved, modest in comparison, say, with the acceptable range of error of cost estimates, then the simplification effected by the rule of thumb may be well worth the price. Even if this is accepted, of course, there remains the critical issue of the social choice of time preference rate, since the particular number chosen is of greatest consequence for decisions among projects of any considerable duration. The choice of time preference rate, essentially involving questions of distribution of welfare among generations, leads us into the literature on optimal savings and away from the subject of this paper.

The Demand for Risky Assets

By IRWIN FRIEND AND MARSHALL E. BLUME*

A striking characteristic of recent research on capital asset pricing is the paucity of empirical work on the determinants of the market price of risk[1] in contrast to the abundance of work on the interrelationships of the risk premiums among different risky assets. The market price of risk will in part depend on the utility functions of individual investors and, except for a special class of functions, on the distribution of wealth among investors.

The relationship between utility functions and wealth of all investors is obviously basic to constructing an aggregate demand function for risky assets. However, there are a multiplicity of other important potential uses, including the derivation of the form of household consumption or saving functions, measurement of the impact of different government, fiscal, or insurance measures on economic welfare, and assessment of the problems in extending single period financial and economic investment decisions to a multiperiod world.

Until recently, most interested economists have seemed to believe that utility functions of individuals were characterized either by constant or decreasing absolute risk aversion and by increasing proportional risk aversion (Section I). The measure of proportional risk aversion used in this paper is the same as the elasticity of the marginal utility of wealth. In recent years, this traditional view of increasing proportional risk aversion has been vigorously questioned by advocates of the *log* utility function which, while still maintaining decreasing absolute risk aversion, implies that proportional risk aversion is constant rather than increasing.

This paper will, for the first time, systematically exploit cross-sectional data on household asset holdings to assess the nature of households' utility functions. The data used are detailed information on assets, income, and other socioeconomic-demographic characteristics for a large sample of households.

Prior to analyzing the survey data, the paper will adapt and extend existing theory to obtain the relationships between the composition of household wealth (both human and nonhuman) and their utility functions. These relationships are suitable for statistical analyses at both the micro and macro levels (Section II). Part of the empirical work is based upon these survey data (Section III). Other work analyzes *ex post* and *ex ante* market returns since the latter part of the nineteenth century to estimate the market price of risk (Section IV). The last part of the paper synthesizes the analyses of the household and market data (Section V).

Our main conclusions are: First, regardless of their wealth level, the coefficients of proportional risk aversion for households are on average well in excess of one and probably in excess of two. Thus, investors require a substantially larger premium to

[1] The market price of risk is the difference between the expected rates of return on the market portfolio of risky assets as a whole and on a risk-free asset per unit of risk of the market portfolio. For purposes of this paper, it turns out that the relevant measure of risk is the variance of returns.

hold equities or other risky assets than they would if their attitudes toward risk were described by logarithmic utility functions.

Second, the paper concludes that the assumption of constant proportional risk aversion for households is as a first approximation a fairly accurate description of the market place. These first two findings imply that the utility function of a representative investor is quite different from those which have often been assumed in the literature. However, it should be pointed out that our conclusion of constant proportional risk aversion follows from our treatment of investment in housing. Other plausible treatments would imply either moderately increasing or moderately decreasing proportional risk aversion.

Third, under tenable assumptions, including that of constant proportional risk aversion, we develop a simple form of the aggregate equilibrium relationship between the relative demand for risky assets and the market price of risk. To determine the actual values of the required rate of return on risky assets, the market price of risk, and the relative value of risky assets would of course entail the specification of supply conditions. For a constant physical supply of both risky and nonrisky assets, the relationship developed in this paper indicates how the required rate of return on risky assets as a whole is determined.

I. Earlier Studies

Economists have generally been convinced that the market utility function has risk-aversion properties somewhere between a negative exponential utility function with constant absolute risk aversion and increasing relative risk aversion, and a constant elasticity utility function with decreasing absolute risk aversion, but with constant proportional risk aversion. The authority generally cited for asserting these bounds for the utility function is Kenneth Arrow (for example, see S. C. Tsiang).

While no one is likely to argue with the plausibility of decreasing absolute risk aversion, the widely held assumption of increasing (or at most constant) relative risk aversion is open to question. At the theoretical level, the denial of the tenability of decreasing relative risk aversion is based on the assumed implausibility of a utility function which is unbounded either from above or from below (see Arrow). However, arguments based upon such bounding conditions may be economically empty. The ultimate justification for such an assumption must rest on the empirical data. The only direct evidence we know of that has been cited to support the assumption of increasing or constant relative risk aversion are the studies which conclude that either the income elasticity or the wealth elasticity of demand for cash balances (usually money narrowly or broadly defined) is at least one (see Arrow). Of this evidence, only the wealth elasticity is at all relevant. Moreover, in view of the existence of liabilities or negative assets in investors' balance sheets, it is more appropriate to relate the total of risky assets, rather than the customary cash balances, to net worth, but this does not appear to have been done in the relevant literature.

The available cross-section studies based on household surveys of assets and liabilities seem to point to a wealth elasticity of liquid assets of well below or close to one if all tangible assets including consumer durables are included in wealth, and lower figures if tangible assets are excluded (for example, see Jean Crockett and Friend, pp. 37 and 55–57). The aggregate time-series data reflecting changes in supply and demand conditions, including those arising from changes in wealth distribution among different groups in the population, appear to be much less pertinent than the cross-section information.[2]

In recent years, the major challenge to the widely held assumption of a market utility function characterized by increasing relative risk aversion has been posed by proponents of the *log* utility function which implies constant relative risk aversion (again associated with decreasing absolute risk aversion). The *log* utility function has been justified in this literature mainly on grounds of the reasonableness of the implicit growth maximization criterion as contrasted with the alleged unreasonableness of mean-variance efficient portfolios.[3]

More recently, in Richard Roll's paper a new set of empirical tests of the implications of the growth-optimum and mean-variance models found that the former performs well in comparison with the latter "but the test results are clouded by the close operational similarity of the two models" (p. 552). Still another set of empirical tests obtained from experimental games suggested that a *log* utility function might characterize individuals with wealth in excess of $200,000, but below that level increasing relative (and decreasing absolute) risk aversion was exhibited. (See M. J. Gordon, G. E. Paradis, and C. H. Rorke.)

II. Theoretical Background for the Empirical Analysis

The literature has shown under various conditions that in equilibrium the market price of risk—the ratio of the expected risk premium on risky assets to the variance of return on those assets—equals the market value of all risky assets times a function of each individual's measure of absolute risk aversion. More precisely, this relationship can be developed for discrete planning periods by assuming either that investors' utility functions are quadratic or that their utility functions are exponential or logarithmic and end-of-period wealth is normally distributed.[4] This relationship takes the form

$$(1) \qquad \frac{E(r_m - r_f)}{\sigma^2(r_m)} = V_{mo}\left[\sum_k E\left(\frac{1}{R_k}\right)\right]^{-1}$$

where r_m is the return on the market portfolio of all risky assets, r_f is the return on the risk-free asset, R_k is Pratt's measure of absolute risk aversion for the kth investor, and V_{mo} is the market value of all risky assets at the beginning of the planning period. Stephen Ross has obtained a similar expression by assuming an infinitesimal planning horizon and no finite changes in value of any asset in an infinitesimal period.[5]

Although the various developments of (1) assumed that the net supply of the risk-free asset was zero, they can easily be generalized to the situation in which this asset has a positive net supply. For mathematical convenience, this generalization will be based upon an infinitesmal horizon model and will make the same assumptions as those made by Ross. Besides the assumption about the distribution of returns mentioned above, perhaps the most critical assumptions include homogeneity of expectations and a frictionless capital market. In a frictionless capital market, all financial assets—both risk-free and risky—are infinitely divisible, can be traded with no transaction costs, and can be sold short with the proceeds available to purchase another asset.

---

[2] Even the time-series analyses are not consistent in indicating a wealth elasticity of cash balances, broadly defined, equal to or greater than one in the period following World War II. See Allan Meltzer, p. 236.

[3] See Henry A. Latané; Nils Hakansson; and Harry Markowitz. For a different theoretical position, see Paul Samuelson and Robert Merton.

[4] See Jan Mossin; John Lintner; and A. P. Budd and R. H. Litzenberger.

[5] This assumption is nontrivial and would exclude such distributions of returns of individual assets as nonnormal stable.

In parallel with Ross's development, the wealth conservation equation for the kth investor, assuming no taxes, would be[6]

$$(2)\quad W_{k,t+dt} = W_{kt}\{1 + [r_f + \alpha_k E(r_m - r_f)]dt + \alpha_k \sigma_m y(t)\sqrt{dt}\}$$

where α_k is the proportion of the net worth of investor k placed in the portfolio of risky assets, σ_m is the standard deviation of the returns on the portfolio of risky assets, and $y(t)$ is a standardized normal random variate.[7] By expanding $U(W_{k,t+dt})$ about W_{kt}, taking expected values and dropping terms involving dt to the power of 2 or more, one obtains

$$(3)\quad E[U(W_{k,t+dt})] = U(W_{kt}) + U'(W_{kt})W_{kt}[r_f + \alpha_k E(r_m - r_f)]dt + \tfrac{1}{2}U''(W_{kt})W_{kt}^2\alpha_k^2\sigma_m^2 dt$$

To determine the optimal value of α_k, the derivative of $E[U]$ is set to zero:

$$(4)\quad U'(W_{kt})E(r_m - r_f) + U''(W_{kt})W_{kt}\alpha_k\sigma_m^2 = 0$$

Recalling that Pratt's measure of relative risk aversion C_k is defined as $W_{kt}[-U''(W_{kt})/U'(W_{kt})]$,[8] (4) can be rewritten as[9]

$$(5)\quad \alpha_k = \frac{E(r_m - r_f)}{\sigma_m^2}\cdot\frac{1}{C_k}$$

In the absence of taxes, (5) could be used to estimate the coefficient of relative risk aversion for investor k given estimates of α_k and the market price of risk. However, if returns from both risky and risk-free assets are taxed at the same rates in any tax bracket[10] and if t_k is the average rate of tax for investor k, equation (2) could be modified to incorporate the tax effect. Repeating the logic underlying (2) through (5) would yield the tax adjusted relationship:

$$(6)\quad \alpha_k = \frac{E(r_m - r_f)}{\sigma_m^2}\cdot\frac{1}{(1 - t_k)C_k}$$

Since r_m and r_f are measured before personal taxes, the assumption of homogeneous expectations assures that if $(1-t_k)\alpha_k$ is constant over all investors, C_k will also be constant. This observation will be used in the next section in conjunction with cross-sectional survey data to assess how C_k varies with net worth.

So far, it has been explicitly assumed that all assets are liquid in that they can be purchased or sold at no cost in any quantity. This assumption is clearly unrealistic for human wealth. David Mayers has shown in a mean-variance world of finite horizons how this assumption can be relaxed to allow for the nonmarketability of human wealth. His insight can be readily applied to the continuous case. To do this, redefine r_m as the return on the portfolio of liquid risky assets and α_k as the proportion of investor k's liquid net worth (total net worth less human wealth) placed in the portfolio of liquid risky assets. Further, define the new terms: h_k as the ratio of the value of the human wealth of the kth investor to his net worth and r_{hk} as the rate of return on the kth investor's human wealth.

---

[6] An intuitive explanation for the appearance of the standard deviation with $\sqrt{dt}$ rather than with dt is that if a time period is subdivided into n subperiods each of duration $\tau = 1/n$, and if the returns over each of these subperiods are independently distributed, then the variance of returns over τ, σ_τ^2 is equal to $1/n$ times the variance of returns σ_t^2 over the initial period. As n approaches ∞, $1/n$ approaches dt, so that σ_τ approaches $\sigma_t\sqrt{dt}$.

[7] Equation (2) implies that the kth individual invests α_k of his assets in risky assets and $1-\alpha_k$ in the risk-free asset. In the type of continuous time model used in this paper, the separation theorem holds.

[8] This measure of relative risk aversion can also be interpreted as the wealth elasticity of the marginal utility of wealth as indicated in the introduction.

[9] Samuelson has obtained a similar expression for the individual investor.

[10] This assumption is tantamount to assuming that capital gains and ordinary income are taxed identically and abstracts from the special tax treatment of homes and tax-exempt securities. However, see fn. 37.

Under these definitions, the wealth conservation equation adjusted for taxes t_k, again assumed the same for all types of income, would be

$$(7)\quad W_{k,t+dt} = W_{kt}\Big\{1 + (1-t_k) \cdot \{(1-h_k)[r_f + \alpha_k E(r_m - r_f)] + h_k E(r_{hk})\}dt + (1-t_k) \cdot [(1-h_k)^2\alpha_k^2\sigma_m^2 + h_k^2\sigma_{hk}^2 + 2\alpha_k h_k(1-h_k) \cdot Cov\,(r_m, r_{hk})]^{1/2} y(t)\sqrt{dt}\Big\}$$

The covariance term allows for the presence of dependencies between the returns on liquid and human wealth. That both the variance of human wealth and the covariances are subscripted by k means that these statistics can vary from one individual to another. Repeating the logic underlying (2) through (5) would yield

$$(8)\quad \alpha_k = \frac{E(r_m - r_f)}{\sigma_m^2} \cdot \frac{1}{(1-t_k)(1-h_k)C_k} - \frac{h_k}{1-h_k}\beta_{hk,m}$$

where $\beta_{hk,m}$ is the ratio of $Cov(r_m, r_{hk})$ to σ_m^2. Thus, $\beta_{hk,m}$ can be interpreted as the slope coefficient of the regression of r_{hk} on r_m. It is interesting to note that the ratio α_k does not depend upon $E(r_{hk})$ but only upon the dependence between r_m and r_{hk}.[11]

Equations (6) and (8) are micro functions for the individual investor and are not the same kinds of relationships as (1), which is an equilibrium condition for the market as a whole—a macro-economic concept. Such macro relationships can be developed from these micro functions by forming a weighted average of α_k over all investors, the weights defined as the ratio of the investor's liquid wealth to the total liquid wealth in the market. If γ_k equals this proportion, if α is defined as the ratio of liquid risky assets to all liquid assets, and if all assets are liquid, the micro relationship (6) would imply

$$(9)\quad \sum \gamma_k\alpha_k = \alpha = \frac{E(r_m - r_f)}{\sigma_m^2}\sum \frac{\gamma_k}{(1-t_k)C_k}$$

Relation (9), which is easily solved for the market price of risk, differs from (1) mainly in that it takes into account taxes, allows the net supply of the risk-free asset to be positive, and is expressed in terms of relative rather than absolute risk aversion.

If one includes human wealth and further assumes that this wealth is illiquid, a similar macro relationship to (9) can be derived by averaging α_k given by (8). The resulting average is

$$(10)\quad \sum \gamma_k\alpha_k = \alpha = \frac{E(r_m - r_f)}{\sigma_m^2} \cdot \left[\sum \frac{\gamma_k}{(1-t_k)(1-h_k)C_k}\right] - \sum \gamma_k \frac{h_k}{1-h_k}\beta_{hk,m}$$

The macro relationship (10), again easily solved for the market price of risk, is quite different from (1) and (9) in that it takes explicit account of the nonmarketability of human wealth.

---

[11] Since the dependence between r_m and r_{hk} is a factor in determining the optimum ratio of risky liquid assets to all liquid assets, it would be anticipated that an investor might be able to improve his expected utility by altering the proportions of the risky liquid assets he holds from those implicit in the market portfolio to take into account differences in the values of the covariances of human wealth and individual liquid assets in the market portfolio. The work of Y. Landskroner indeed shows this to be the case. Whether (8) results in an expected utility close to the optimum depends upon the correlation of the optimal portfolio of risky liquid assets and the market portfolio. If this correlation were very close to 1.0, for instance, it would be possible to construct a portfolio of the market and the risk-free asset which would have a probability distribution very similar to the optimal portfolio of liquid assets. Numerous empirical studies have demonstrated that the returns on portfolios of a large number of securities are highly correlated with the market portfolio.

It should be noted that equations (9) and (10), and the simplifications of these equations presented subsequently, represent aggregate equilibrium relationships between the relative demand for risky assets and the market price of risk. The market price of risk at the macro level is not given, as it may be at the micro level, but is determined jointly with the aggregate ratio α of liquid risky assets to all liquid assets. For example, assuming a constant physical supply of both risky and nonrisky assets, α is determined by $E(r_m)$ and r_f. Equations (9) and (10) indicate how $E(r_m)$ and α are related to C_k, the distribution of wealth γ_k, tax rates t_k, σ_m^2, and r_f.[12]

If an investor's coefficient of relative risk aversion is assumed independent of γ_k and this coefficient is also independent of his average tax rate, (9) can be vastly simplified. This assumption of constant proportional risk aversion on the average is considerably more general than the assumption that all investors have the same value for C_k in that C_k can be a function of characteristics of investors which are independent of γ_k and t_k.

Specifically, let it be assumed that C_k is given by

$$\frac{1}{C_k} = \frac{1}{C} + \epsilon_{ck} \tag{11}$$

where ϵ_{ck} is a mean-zero disturbance independent of γ_k and t_k. The symbol C defined by (11) can be interpreted as the harmonic mean of C_k. Let us first simplify (9) by substituting (11) into it to obtain

$$\alpha = \frac{E(r_m - r_f)}{\sigma_m^2} \cdot \left[\frac{1}{C}\sum \frac{\gamma_k}{1 - t_k} + \sum \frac{\gamma_k \epsilon_{ck}}{1 - t_k}\right] \tag{12}$$

The application of expected value operators to (12) causes the second summation in the brackets to go to zero. Since the sum of the γ_ks is one, the reciprocal of the first summation might be termed the weighted harmonic mean of $(1-t_k)$. Designating this mean as $1-t$ and solving for the market price of risk, (12) takes the simplified form

$$\frac{E(r_m - r_f)}{\sigma_m^2} = \alpha C(1 - t) \cdot \tag{13}$$

If in addition to the assumption of constant proportional risk aversion (on the average) it can further be assumed that $\beta_{hk,m}$ and ϵ_{ck} are independent of the level of human wealth of the kth individual, (10) can likewise be vastly simplified. To do this, note first that the terms α, $(\gamma_k h_k)/(1-h_k)$, and $\gamma_k/(1-h_k)$ can be rewritten as R/L, H_k/L, and W_k/L, respectively, where H_k is the value of the kth investor's human wealth, W_k his net worth, R the total value of all risky liquid assets, and L the total value of all liquid assets. With these identities, the simplification of (10) proceeds by substituting (11) into (10), taking expected values, substituting these identities, and solving for the market price of risk. The resulting expression is

$$\frac{E(r_m - r_f)}{\sigma_m^2} = \left[\frac{R}{W^*} + \beta_{hm}\frac{H}{W^*}\right] C \tag{14}$$

where W^* is $\sum W_k/(1-t_k)$ or a tax adjusted sum of all wealth and β_{hm} is defined as $E(\beta_{hk,m} | H_k)$, assumed the same for all investors.[13]

---

[12] This can easily be seen by writing in a one-period model

$$\alpha = \frac{E(R_m)}{1 + E(r_m)} \div \left[\frac{E(R_m)}{1 + E(r_m)} + \frac{F}{1 + r_f}\right]$$

where $E(R_m)$ represents the expected dollar return over the period on the available supply of liquid risky assets at the beginning of the period, and F represents the corresponding known dollar return on riskless assets. The constant physical supply of liquid risky assets and risk-free assets are measured by $E(R_m)$ and F, respectively.

[13] Though (14) was developed under the restrictive assumption that the sole decision of the individual was how much of his liquid assets to place in the market

(over)

These simple equilibrium expressions are valid if investors' utility functions are characterized by constant proportional risk aversion on the average as specified in (11). If valid, (13) and (14) would seem to offer tractable ways to estimate C from time-series data.[14] They also provide extremely simple forms of the aggregate equilibrium relationship between the relative demand for risky assets and the market price of risk.

III. The Analysis of the Survey Data

The micro relationships just developed lend themselves to the use of cross-sectional data in ascertaining whether or not C_k, the coefficient of proportional risk aversion, is invariant on the average to investors' net worth. After describing the cross-sectional data, we will first examine the behavior of C_k employing (6) which implicitly assumes that all wealth is liquid and then will assess it employing (8) which explicitly accounts for the nonmarketability of human capital.

The cross-sectional data to be analyzed come from the 1962 and 1963 Federal Reserve Board (*FRB*) Surveys of the Financial Characteristics of Consumers and Changes in Family Finances. These surveys, which oversampled the upper income groups, collected for more than 2,100 households detailed information on the value of their assets and liabilities at the end of both 1962 and 1963 and on the sources and amounts of income in both of these years.

From these data, the study constructed three different types of balance sheets at the end of 1962. The first type included all assets and associated liabilities with the exception of human wealth and homes.[15] The second excluded only human wealth. The third included not only homes, but also an estimate of human wealth. These balance sheets, expressed as ratios to the corresponding measures of net worth, are summarized in Tables 1–3 by net worth categories. Changes in the definition of wealth will, of course, move households from one wealth class to another.

In checking the validity and reasonableness of the data, it was observed that a few households received substantial salaries from closely held businesses in which they had active interests. Since some part of these salaries might more properly be classified as dividends or return on capital, any salaries from such closely held businesses in excess of $25,000 were valued as perpetuities at 10 percent and added to equity. To determine how sensitive the results are to this adjustment, the subsequent analyses were replicated on a subsample which excludes any households which own such businesses. The conclusions were virtually unchanged.[16]

Only households with a net worth in excess of $1,000 were included. Since such households have a predominant impact upon the market for assets, this restriction would have little effect upon the value of the variables in the macro relationships

---

portfolio of liquid risky assets, Landskroner has shown that if r_0, the return on an asset uncorrelated with the return on the market portfolio of risky assets, is substituted for r_f and is also uncorrelated with the return on human capital, (14) holds in the more general case where an investor's decision variables include not only how much to put into risky liquid assets, but also how much to place into each risky liquid asset.

[14] To utilize (13) in a time-series, the weighted harmonic mean of $(1-t_k)$ might be approximated by the ratio of total disposable income to total adjusted gross income. For the survey of households to be examined in the next section, the weighted harmonic mean would be 0.787 while the ratio of total disposable income to total adjusted gross income would be 0.859 which is close to the 0.871 implied by the *Statistics of Income*. Thus, if this harmonic mean is representative of the population, the ratio of total disposable income to total adjusted gross income would be about 10 percent greater than the harmonic mean. This figure of 10 percent might be useful in adjusting the time-series available from the *Statistics of Income* to that required by (13).

[15] With homes are included automobiles which represent only a minor proportion of assets except possibly for the lowest wealth groups.

[16] See fn. 21.

Table 1—Average Ratios of Assets and Selected Items to Household Net Worth Exclusive of Homes (and Associated Mortgages) for Households Classified by Net Worth[a]

December 31, 1962

	Net Worth (Thousands of Dollars)

Ancillary Statistics						
$(1-t_k)\alpha_k$[f]	0.285	0.601	0.749	0.763	0.677	0.650
Number of Households	523.	477.	68.	100.	69.	103.

[a] These averages are weighted by the inverse of the sampling probability for each household. These sampling probabilities have been adjusted for nonresponse and other factors. The net worth used in classifying households is defined in the same terms as the balance sheet.

[b] Includes checking and other commercial bank accounts, savings and loan savings accounts, credit union savings accounts, and mutual savings accounts.

[c] Includes U.S. Treasury Bills, notes and certificates, the withdrawal value of profit sharing and retirement plans, credit balances in brokerage accounts, and risk-free assets held in trust accounts. Risky assets held in trust accounts are included in the appropriate category of direct holdings, except that when they could not be classified in this manner, they were included in miscellaneous risky assets.

[d] Includes long-term corporate, state and local and U.S. government bonds (other than savings bonds).

[e] Includes investment real estate assets and miscellaneous assets, such as patents, etc.

[f] The symbol α_k is defined as the ratio of the sum of the mixed-risk and risky assets to net worth for investor k. The symbol t_k is the average federal tax rate for investor k as estimated by the procedure devised by the Survey of Financial Characteristics of Consumers. The only difference was that realized capital gain income or losses were included in adjusted gross income in this paper unlike the original procedure. The original survey ignored this type of income in calculating the tax rate.

(13) or (14). Yet, it appears to improve the quality of the survey data by eliminating those households who may have underreported their assets or whose assets were temporarily lower than normal.

A crude estimate of human wealth was given by the discounted value of the average labor income in 1962 and 1963 which was then assumed to grow at 4 percent per year. The discount rate was taken to be 10 percent. If a person was less than 65, he was assumed to retire at 65. If he was working and over 65, he was assumed to continue to work for four years; if over 69, three years; if over 74, two years; and if over 79, one year. The sensitivity of the subsequent results to this arbitrary method of calculating human wealth will be examined, and it will turn out that within broad ranges of discount rates and growth rates

[b] Includes automobiles.

the results are substantially unaffected.

If the micro relationship (6) were to hold, an estimate of the market price of risk times the reciprocal of the coefficient of relative risk aversion $[E(r_m-r_f)/\sigma_m^2]C_k^{-1}$ is given by $\alpha_k(1-t_k)$. The assumption made in the last section that all investors agree on the value of the market price of risk means that $\alpha_k(1-t_k)$ provides an estimate of C_k^{-1} up to a multiplicative positive constant, so that $\alpha_k(1-t_k)$ can be used to assess how C_k^{-1} and, thereby, how C_k varies with net worth.[17] Using either of the first two balance sheets, which do not include human capital, the cross-sectional data provide estimates of $\alpha_k(1-t_k)$. Since (6) does not take account of the nonmarketability of human wealth, the analysis based upon (6) will not include this kind of wealth. It might be mentioned that virtually all empirical applications of

---

[17] If $E[C_k^{-1}]$ were to decrease with increases in net worth W_k, it is not necessary that $E(C_k)$ would increase. Yet, if the distributions of C_k given W_k, $P(C_k|W_k)$, remain unchanged as W_k increases except for location, it can be shown that $E(C_k)$ would increase with increases in W_k. This proposition follows from noting that if for fixed ϵ_k, $[E(C_k)+\epsilon_k]^{-1}>[E(C_k)'+\epsilon_k]^{-1}>0$, $E(C_k)+\epsilon_k<E(C_k)'+\epsilon_k$. Since $P(C_k|W_k)$ is unchanged except for location, the distributions of ϵ_k will be the same at each level of W_k. Taking the definite integral of these two inequalities with respect to the distribution of ϵ_k yields the desired result.

TABLE 3—AVERAGE RATIOS OF ASSETS AND SELECTED ITEMS TO HOUSEHOLD NET WORTH INCLUSIVE OF HUMAN WEALTH AND HOMES CLASSIFIED BY NET WORTH[a]

December 31, 1962

	Net Worth (Thousands of Dollars)

portfolio theory have ignored human wealth in spite of its obvious importance to the demand for risky assets.

In interpreting the meaning of these numbers, it should be noted that the derivation of (6) assumed that all assets are acquired for investment purposes, can be unambiguously dichotomized as risky or risk-free, are subject to the same schedule of income taxes, and are infinitely divisible. For analyses of the composition of wealth inclusive of homes, these assumptions may be so unrealistic as to place serious restrictions on the validity of (6).

Contrary to the implicit treatment of assets in our model and in capital asset pricing theory generally, homes are typically acquired by households for consumption as well as investment purposes. Moreover, the lack of tax on the imputed income from owning a home as well as other subsidies make the tax rate assumption highly questionable. Furthermore, a house involves a substantial investment and for a person with limited liquid assets, the incurrence of more debt than he might normally want to have. In the absence of an adequate rental market, the purchase of a home may be the only way of obtaining the desired type of housing. Holding utility functions constant, these factors would tend to increase the values of α_k for the

[a] Includes automobiles.

[b] The dummy variables, assuming the value of 1.0 if the characteristic is applicable to the head of the household and 0.0 otherwise, are for age (less than or equal to 25 and 5-year intervals from 25 to 65), for education (grade school or less, some high school, high school graduate, some college, or college graduate), and for occupation (self-employed, employed by others, retired, farm operator, not gainfully employed, and employer unknown).

lower wealth groups relative to those for the upper wealth groups if the investment in a home is assumed to be risky.[18]

Since investments in homes are not strictly compatible with the assumptions underlying (6), homes have been treated in three different ways in the empirical work: not as an investment asset; as a risky asset where the relevant investment is measured by the household's equity in the home; and as a risky asset where the investment is measured by the gross market value of the home. Another possibility would be to assume that households consider homes to be riskless assets, but this seems a less tenable assumption than the ones we have utilized.

Within the context of the model embodied in (6), perhaps the most appropriate measure of a household's investment in housing is its equity value. First, if an investor views a mortgage and a house as a package, it may well be that he regards only his equity at risk. Second, the use of equity is more in the spirit of infinitely divisible assets than the use of total assets. Nonetheless, the results of alternative assumptions are presented.

Tables 1 and 2 present averages of the estimated tax adjusted ratio $(1-t_k)\alpha_k$ by net worth classes for varying treatments of housing. Human wealth is not included. In addition, Table 4 presents the slope coefficients of the regressions of $(1-t_k)\alpha_k$ on the logarithm of net worth.[19] The α_k in these tables are ratios of risky and mixed-risk assets to net worth. Both simple regressions and regressions which control with dummy variables for the possible interaction between net worth and three socioeconomic factors (age, education, and occupation) are presented. Whether or not these dummy variables are included, the slope coefficients on the logarithm of net worth are not much different.[20]

---

[18] Housing presents other difficulties in applying the micro relationships developed in the last section. First, since an investor values a house not only for its monetary rewards but also for its consumption value, it may be difficult to aggregate returns from housing with those from other assets. Second, the purchase of a home with a large mortgage permits an investor to hedge against changes in housing costs and in the costs of borrowing funds.

[19] In the first attempt at running these regressions, the sampling probability associated with each household was used to adjust for heteroscedasticity on the assumption that the reciprocal of the sampling probabilities in each stratum was picked to be negatively related to the variation within the stratum. The correlations of the absolute value of the residuals with these reciprocals revealed that there was substantial heteroscedasticity present in the regressions. All regressions reported in the paper are unweighted and exhibited little evidence of heteroscedasticity.

The relationship of $(1-t_k)\alpha_k$ to net worth varies according to whether housing is included, and if included, how measured. For the narrowest definition of wealth exclusive of human wealth and homes, there is overall a significant positive relationship to net worth (see Table 4). A closer analysis, however, indicates that most of this positive relationship stems from households with net worth of less than $500,000 and that for households of greater means, the ratio shows a slight tendency to decrease (see Table 1). This behavior would be consistent with decreasing proportional risk aversion at least through net worth classes up to $500,000. This result is not affected appreciably if mixed assets were combined with risk-free rather than with risky assets. For the broader definition of wealth including housing as a risky asset but excluding human wealth, the ratio of $(1-t_k)\alpha_k$ is practically invariant to net worth if housing is measured by its equity value, and negatively related to net worth if housing is measured by its full value (see Table 4). These findings are consistent with constant proportional and increasing proportional risk aversion, respectively.[21] If housing is included as a risk-free asset, the tendency toward decreasing proportional risk aversion would be even greater than indicated by Table 1.

There are several potentially important biases in these findings. First, contrary to the assumptions of the model, individuals do not all hold the same portfolio of risky assets. Consider an individual whose portfolio of risky assets is perfectly correlated with the market portfolio of risky assets but is less volatile—that is, has a portfolio *beta* coefficient of less than 1.0. Since the risky portfolio of reference is the market portfolio, the calculated value of α_k would overstate the relative degree of risk in his portfolio. Likewise, if he were to hold a portfolio of risky assets with a *beta* greater than one, the calculated value of α_k would understate the degree of risk. The evidence in our 1975 paper indicates that households with lower incomes and presumably less wealth tend to hold portfolios of stocks with smaller portfolio *betas* than their richer counterparts although their portfolios are less well diversified.

Second, life insurance is not handled satisfactorily in this analysis since only the immediately realizable portion is treated as a risk-free asset. Life insurance does not conveniently fit into the dichotomy of risk-free and risky assets, and some other mode of analysis is required to handle this type of asset. However, the net surrender value of life insurance probably represents a significant understatement of the value of insurance as a device for reducing risk. Since life insurance is relatively much more important in the lower than in the upper net worth classes, correction for this deficiency of the model would again tend to change the results in the direction of decreasing proportional risk aversion.

Third, the calculated α_k might differ from its permanent value because of transitory elements. If a transitory reduction in net worth left unchanged the value of risky assets, the calculated α_k would be biased upwards. This situation might apply to an individual who was faced with a temporary reduction in net worth and because of transaction costs chose to reduce his risk-free assets. However, if he reduced only risky assets, the calculated α_k would be biased downwards. Since the former case is probably more prevalent for families of lower net worth and this type of transitory phenomenon is more likely to apply to these households, correcting for this possible bias would be expected to change the results in the same way as the previous bias.

---

[20] Though these comparative results indicate that the socioeconomic factors are roughly orthogonal to the logarithm of net worth, this does not mean that C_k^{-1} could not vary with these factors.

[21] The qualitative results are unchanged if households with closely held businesses are excluded. For instance, following the same order as in Table 4, the estimated coefficients on the logarithm of net worth would be: 0.076, −0.004, and −.250 with respective t-values of 8.4, −.61, and −11.48. These coefficients are roughly the same as those reported for the full sample. The regressions were also rerun with dummy variables included for age, education, and occupation. There is little change in the estimated coefficients on the logarithm of net worth.

Fourth, the model made the assumption that the tax rate on risky assets was the same as that on risk-free assets. In fact, the tax rate on risky assets tends to be less than that on risk-free assets. While the magnitude of this bias seems to be small, it results in an understatement of C_k.[22] However, it is not clear how this understatement varies with net worth.

To this point, the empirical analyses have ignored human wealth. The micro relationship (8) incorporates such wealth and can be used to examine the behavior C_k. Rearranging (8) yields

$$\text{(15)} \quad \frac{E(r_m - r_f)}{\sigma_m^2}\frac{1}{C_k} = (1 - h_k)(1 - t_k)\alpha_k + h_k(1 - t_k)\beta_{hk,m}$$

If $\beta_{hk,m}$ were known, the right-hand side of (15) could be used to analyze the relationship of C_k^{-1} to net worth. The variable $\beta_{hk,m}$, however, is not known, so that some other tack must be taken.

This other tack will be to assume the validity of two stochastic relationships and use these in conjunction with (15) to derive an empirically estimable regression. For the net worth class i, the first relationship takes the form

$$\text{(16)} \quad (C_k)^{-1} = (C^i)^{-1} + \eta_{ck}$$

where η_{ck} is a mean-zero disturbance independent of h_k and t_k, and C^i is the harmonic mean of C_k in the ith net worth class. This assumption is like the assumption of constant proportional risk aversion on the average, as embodied in (11), except that it only pertains to a single net worth class. Again for net worth class i, the second relationship takes the form

$$\text{(17)} \quad \beta_{hk,m} = \beta^i_{hm} + \eta_{hk}$$

where η_{hk} is a mean-zero disturbance independent of h_k and t_k, and β^i_{hm} is the mean of $\beta_{hk,m}$ in the ith net worth class.

The substitution of (16) and (17) into (15) with some simplification yields the regression

$$\text{(18)} \quad (1 - h_k)(1 - t_k)\alpha_k = \frac{E(r_m - r_f)}{\sigma_m^2}\frac{1}{C^i} - \beta^i_{hm}h_k(1 - t_k) + \mu_k$$

where μ_k is defined to be $[E(r_m - r_f)/\sigma_m^2]\eta_{ck} + h_k(1 - t_k)\eta_{hk}$. The independent variable, $h_k(1-t_k)$, and the dependent variable, $(1-h_k)(1-t_k)\alpha_k$, can be estimated from the cross-sectional data. The constant term allows an analysis of the relationship of the coefficient of proportional risk aversion to net worth class, and the slope coefficient gives an estimate of β^i_{hm}. It is easily verified that under the assumed stochastic processes, μ_k has an expected value of zero and is uncorrelated with the independent variable, so that the estimated coefficients will be unbiased.[23]

Using the total sample of households, regression (18) was first estimated for each of the six net worth classes inclusive of human wealth and with homes measured

---

[22] See fn. 37.

[23] The formula for μ_k would on the surface suggest that (19) suffers from some form of heteroscedasticity. Though this is true because of the way in which (17) and (18) were defined, it would be easy to redefine the variance of η_{hk} as a function of $h_k(1-t_k)$ so as to make (19) homoscedastic. Thus, the apparent heteroscedasticity of (19) is artificial. Further, the discussion of (19) at this point abstracts from measurement error in h_k.

TABLE 5—ESTIMATED COEFFICIENTS AND OTHER STATISTICS FOR REGRESSIONS OF THE FORM[a]

$$(1 - h_k)(1 - t_k)\alpha_k = \frac{E(r_m - r_f)}{\sigma_m^2}\frac{1}{C^i} - \beta^i_{hm}h_k(1 - t_k) + \eta_k$$

[c] Numbers in parentheses are standard errors.

by their equity value (see Table 5).[24] If unbiased, the constant terms indicate that the coefficient of proportional risk aversion on the average increases with net worth. The magnitude of the increase is not large. The estimate of $(C^i)^{-1}$ for those households with net worth in excess of $1 million is 33 percent less than the estimate for those households with net worth between $1 and $10 thousand. The estimates of β^i_{hm} tend to decrease as net worth increases starting at 0.775 for the lowest net worth class and ending at 0.603 for the highest net worth class.

There are several potentially important biases in these results. The first type pertain to violations of the assumptions used in developing (18). The second type pertain to limitations of the survey data. Turning to the first type, the assumptions implied that μ_k, which is a weighted sum of the deviations of $(C_k)^{-1}$ and $\beta_{hk,m}$ from their group means, is independent of $h_k(1-t_k)$ within a net worth class. This implication probably is not strictly true. For instance, households in the same net worth class with a lower proportion of their wealth in human capital might be expected to have lower tax rates which would tend to induce a correlation between η_k and $h_k(1-t_k)$. The possibility that the coefficient of proportional risk aversion might vary with socioeconomic factors would only cause a misspecification of (19) if these factors were correlated to h_k and t_k within a net worth class. Perhaps the most obvious socioeconomic factor which might be correlated with h_k and probably t_k within a class is the employment status of the members of the household. To determine the importance of this obvious misspecification, regression (18) was rerun on the sample of households reporting some income from salaries or wages. The results are not much different from the regressions for the total sample (see Table 5). For three out of six classes, the constant term was larger than before, while for the other three it was less, and the changes are not systematically related to net worth.

---

[24] If housing is measured instead by market value, the results are not much different. From lowest to highest net worth class, the constant terms would have been 0.810, 0.793, 0.634, 0.623, 0.530, and 0.500.

Let us now turn to the second type of biases which stem from limitations of the sample data. There are at least five principal problems. First, the balance sheets collected do not contain any estimate of the value of social security or pension fund benefits. Second, the value of relief payments is omitted. The importance of this omission is likely to be significant only in the lowest net worth class. Third, the value of human wealth may be misstated due to incorrectly assumed discount rates and growth rates.[25] Fourth, there may be transitory elements in the value of human capital. Fifth, the data do not allow an unambiguous determination of the return from closely held businesses attributable to wages. Taking the last problem first, (18) was reestimated for households with no closely held businesses. The results were unchanged.[26]

The first four problems all reduce logically to misstatements of the values of h_k and $\beta_{hk,m}$. In the model, social security and pension funds are assets over which a household has no control, so that formally these assets should enter into a more broadly construed h_k and would increase the value of this term. If it is assumed that the return on social security is uncorrelated with the return on the market portfolio of liquid risky assets, the inclusion of social security would reduce the value of a more broadly defined $\beta_{hk,m}$. Since pension funds are generally tied more directly to wage income, as a first approximation it is probably not too far from the mark to assume that their inclusion would not change $\beta_{hk,m}$ by much. The use of an incorrect discount rate or the inclusion of transitory elements would probably cause a misstatement in h_k but not necessarily in $\beta_{hk,m}$.

The total differential of (15) provides a way to measure the impact of these potential problems. Assuming dt_k and $d\alpha_k$ are zero in that t_k and α_k, derived from the household data, are known, the total differential takes the form

$$(19)\quad d\,\frac{E(r_m - r_f)}{\sigma_m^2}\,\frac{1}{C_k} = [(1 - t_k)\beta_{hk,m} - (1 - t_k)\alpha_k]dh_k + h_k(1 - t_k)d\beta_{hk,m}$$

The coefficients on $d\beta_{hk,m}$ can be estimated by net worth class as the means of $h_k(1-t_k)$ given in Table 5. Likewise from Table 5, the coefficients on dh_k by net worth class starting with the lowest can be estimated as: 0.179, 0.112, −0.071, 0.003, −0.152, and −0.154.

---

[25] The calculation of the value of human wealth made no adjustment for the probability of death before normal retirement. Formally, this is equivalent to assuming an incorrect discount rate and will be subsumed under this problem.

[26] From lowest to highest net worth class, the constant terms were estimated respectively as 0.711, 0.635, 0.541, 0.580, 0.522, and 0.449.

Replacing the total differentials in (19) by finite differences and recalling that h_k is measured as a proportion, it is seen that $|\Delta h_k|$ would have to be extremely large to have much effect upon the relationship of the market price of risk times $(C^i)^{-1}$ to net worth. Thus, the conclusions would appear robust to large errors in the assumed discount and growth rates.

Correcting for the omission of social security benefits may have an important impact and together with the biases previously discussed might easily change the conclusion to one of constant proportional risk aversion on the average. To determine the magnitude of such a correction, let us assume that the average value of social security benefits within a net worth class in 1962 was \$15,000.[27] Also assume that the value of social security does not change in any predictable way with changes in the value of the market portfolio, and that the net worth of the typical household in a net worth class is the midpoint except for \$2 million for the class with the largest net worth. On the basis of these assumptions, the estimates of $[E(r_m-r_f)/\sigma_m^2](C^i)^{-1}$ would change to 0.609 for the 1–10 thousand dollar class,[28] 0.583 for the 10–100 class, 0.561 for the 100–200 class, 0.592 for the 200–500 class, 0.521 for the 500–1,000 class, and 0.495 for the class of greatest wealth. These adjusted figures show considerably less evidence of increasing proportional risk aversion on the average. Assigning a larger value to social security benefits and adjusting for the other biases discussed above might even change the conclusion to decreasing proportional risk aversion.

To summarize, for what we regard as the most appropriate treatment of investment in homes and human wealth within the context of our model, the unadjusted results give some evidence of increasing proportional risk aversion on the average. Yet, the magnitude of this increase is not great. Corrections for the various deficiencies of the theoretical model, the econometric analyses, and the sample data would on balance tend to make the results closer to constant proportional risk aversion and might even produce evidence of moderately decreasing proportional risk aversion. Perhaps the most accurate single statement is: if there is any tendency for increasing or decreasing proportional risk aversion, the tendency is so slight that for many purposes the assumption of constant proportional risk aversion is not a bad first approximation.

IV. The Market Price of Risk

To assess numerical values for the coefficients of proportional risk aversion, the results in the previous section must be augmented with an assessment of the market price of risk, namely $E(r_m-r_f)/\sigma^2(r_m)$. This section will employ two different techniques to formulate such an assessment. The first will utilize realized rates of return on stocks and fixed interest obligations, while the second will attempt

---

[27] This estimate of value is based upon the following assumptions: The average household is headed by a person 45 years old and consists of a spouse and two children with average age of 10 years. Using the 1941 CSO table as in *CRC Standard Mathematical Tables* with a 2.5 percent interest rate and assuming maximum benefits with no increases in the future, the retirement portion was estimated roughly to be \$13,000 which represents an overstatement in view of the assumption of maximum benefits. The ancillary survivorship and disability benefits are more difficult to estimate but seem well under the 50 percent of retirement benefits as shown in government compilations. As a result, we have used an overall, probably somewhat conservative estimate of \$15,000 for the combined value of retirement and ancillary benefits. The use of 2.5 percent interest rate is consistent with the maintenance of the real value of the benefits over time.

[28] This number was calculated by noting that the inclusion of social security benefits would cause an increase of 0.487 in the value of h_k and a decrease of 0.690 in the value of β_{hm}. Applying these changes to (19) results in a decrease of 0.133, which when subtracted from 0.742 gives the adjusted estimate in the text.

TABLE 6—AVERAGE ANNUAL ARITHMETIC RATES OF RETURN AND STANDARD DEVIATIONS OF ANNUAL RETURNS 1872–1971

[a] From 1926, the figures are estimated from the Standard & Poor's Stock Indexes. For earlier years, the data are from *Common-Stock Indexes*. The Cowles *Index* was converted to the Standard & Poor's base by adjusting overlapping figures. The relative for the first quarter of the t-th year was taken to be $i_1=[P_1+\frac{1}{4}(D_1/P_1)P_1]/P_0$ where P_1 and D_1/P_1 are stock price and annualized dividend yield at end of quarter and the return for the year derived from the product of the four quarterly returns.

[b] Semiannual relatives were estimated as $(P+\frac{1}{2}C)/100$, where C is the coupon rate on a new 20-year bond sold at par and P is the price at the end of the 6 months. The coupon rate C was estimated as the yield to maturity given by Standard & Poor's for High Grade Corporate Bonds. The price P was calculated using the coupon rate C and the yield to maturity given by Standard & Poor's at the end of the 6 months on the assumption that such a yield would be appropriate for a bond with 19 years and 6 months to maturity. Multiplying successive pairs of these relatives yields estimates of the annual returns.

[c] The βs are derived from semiannual regressions of the form $r_b=\alpha+\beta r_m$ where r_b and r_m are annual rates of return on corporate high grade bonds and composite stocks, respectively.

[d] Prime Corporate Bonds 1-Year Maturity February Average from Sidney Homer, pp. 366–67, updated by Salomon Brothers.

to develop direct *ex ante* measures. Common stocks on the New York Stock Exchange (*NYSE*) will be used as the principal proxy for the market portfolio of risky assets partially because of the importance of these stocks in the actual market portfolio, but more pragmatically because of the lack of data on returns for most other risky assets. Nonetheless, the market price of risk will also be estimated using similar techniques with data from the bond market to confirm the estimates from the *NYSE* data.

For both industrial and all or composite *NYSE* common stocks, Table 6 shows for the past 100 years, 1872–1971, and selected subperiods, arithmetic averages of annual realized rates of return[29] as well as the standard deviations of these rates. The annual returns, which assume the quarterly reinvestment of dividends, are estimated from the work of the Cowles Commission prior to 1926 and, thereafter, from Standard and Poor's sources. The returns prior to 1926 may be less accurate. Over the past hundred years, the average annual return for the composite stocks was 9.7 percent and for the industrial stocks, 11.3 percent. The standard deviations of these annual returns were 0.19 and 0.22, respectively.

---

[29] These average rates of return would represent unbiased estimates of one-period holding returns if stationarity is assumed. To assess the sensitivity of these numbers to different horizons and since the arithmetic

Also included in Table 6 are corresponding mean annual returns and standard deviations for high grade corporate bonds. The only differences are that coupons are reinvested semiannually rather than quarterly and only the last 70 years are covered. The mean annual return on these bonds over the years 1902–71 was 4.0 percent which compares to a range of 10.7 to 12.8 percent for common stocks over the same period. In fact, in every one of the seven decades covered, stocks beat bonds and sometimes by substantial margins. However, the standard deviations of annual returns on bonds were always less than on stocks.

As a further check on the relationship of the bond and the stock markets, the semiannual returns for the bonds were regressed upon the corresponding returns for the *NYSE* composite stocks.[30] The slope coefficients or *beta* coefficients are displayed in Table 6 and indicate that the returns on bonds usually tend to fluctuate with those on stocks except in the 1952–61 decade when the coefficient is negative. Over the entire 70-year period, the *beta* coefficient is 0.078 which would imply, if the capital asset pricing model held, that the expected risk premium on bonds is 7.8 percent of that on stocks.[31]

Using the mean annual returns and the standard deviations calculated in the corresponding period, estimates of the market price of risk were derived. These estimates —as well as the risk-free rates—are contained in Table 6. The availability of a reliable series for the risk-free rate confined these estimates to the period after 1902. The estimates of the market price of risk over the longest period 1902 to 1971 were 1.7 for the composite stocks and 1.5 for the industrials, with not much different values for the 1902–61 period immediately preceding the date of the *FRB* survey. The estimate for the bond market was 2.3. It might be argued that these estimates are biased downwards because the variance of returns is estimated from a segment of the market of risky assets which would not reflect the full benefits from diversification. Additionally, assets which are both more and less risky than *NYSE* common stocks have been excluded in deriving the average risk premiums. It is difficult to assess the bias associated with these exclusions.[32]

The sampling errors in these estimates are undoubtedly large. To obtain some idea of the magnitude, the estimates of the market price of risk might be conceived of

---

mean raised to the appropriate *n*th power to obtain an *n*-year return can yield a seriously upward biased estimate of expected return over an *n*-year period (see Blume, 1974), an average of five-year returns over the 1872–1971 period (yielding a return relative of 1.587 for the composite index) was compared with the fifth power of the average annual returns (1.592), with little difference in results.

[30] For a discussion of the specification of this type of regression, the reader is referred to Blume (1970).

[31] Over the 1902–71 period, the average annual risk premium on *NYSE* composite stocks was 0.0720. Multiplying this figure by 0.078 would yield an expected risk premium for bonds of 0.0056, which compares to the actual average annual risk premium on bonds of 0.0047.

[32] The market price of risk was also estimated using, instead of variance of returns, the variance of the difference of the annual return and the risk-free rate. If the risk-free rate were constant over time, the two variances would, of course, be the same. These alternative estimates were marginally lower. For the period 1902–71, this alternative estimate was, for instance, 0.04 smaller for the composite stocks than that presented in Table 6.

as drawings from some underlying probability distribution. Using this approach, the average of the seven decade estimates for the composite stocks is 2.4 which is somewhat larger than the estimate derived from the total period reflecting the large sampling error and possibly some nonstationarities in the distribution over time. The standard deviation of this average is 1.2. If the market price of risk were normally distributed, this would mean that there is an 0.88 probability that the true value of this parameter is greater than 1.0. The corresponding average and standard deviation for the industrials are 3.2 and 1.9, respectively.

An alternative way to assess the market price of risk is to develop *ex ante* measures of the expected returns on risky assets and the variance of those returns. To this end, *ex ante* measures of expected return were developed by adding the current yield to an estimate of the future growth rate of earnings per share.[33] The future growth rate was estimated by the arithmetic and by the geometric mean of the annual growth rates over the prior 10 years.[34] For the 70 years ending in 1971, the mean estimate of the expected annual return for the composite stocks ranged from 13.0 to 9.0 percent, depending upon the way in which the future growth rate of earnings was estimated.[35] It might be recalled that the corresponding mean of annual realized returns was 10.7 percent. For comparison, the yield to maturity on high grade corporate bonds is also given in Table 7.

These estimates of expected rates of return for composite stocks were used to derive an estimate of the market price of risk for each of the 70 years from 1902 through 1971. Subtracting the risk-free rate appropriate to the year from these expected returns yielded 70 risk premiums, which were then divided by estimates of the variance of the return for these stocks. These variances were estimated from the 10 realized annual returns immediately preceding the year for which the expected return was assessed. Table 7 presents the average of these 70 estimates of the market price of risk as well as averages for selected subperiods. The average covering the 70 years ending in 1971 was 3.1 using the arithmetic estimate of *ex ante* expected return and 2.0 using the geometric, which are again greater than 1.0 though somewhat higher than the figures derived from realized returns.

To obtain some feeling for the magnitude of the sampling errors associated with these averages for the overall period, the standard deviation of the mean was calculated using every tenth estimate of the market price of risk from 1901 through 1971. Using every estimate instead of every tenth would have resulted in a downward biased estimate of the standard deviation unless explicit account was taken of the fact that successive estimates are based in part upon the same data. The standard deviation of the mean was 0.99 for the market price of risk based upon the arithmetic rate of growth in earnings and 0.87 for the geometric rate of growth. Assuming these standard deviations of the mean can be applied to the means of the 70 annual estimates (though there is reason to believe the true standard deviations would be less), the probability that the market price of risk using arithmetic rates of growth is greater than 1.0 would be 98

---

[33] Implicit in this formulation are the assumptions: 1) Earnings grow at a constant rate in perpetuity. 2) The payout ratio and discount rates are constant.

[34] Estimates using only 5 prior years of data gave unreasonably low rates of return in the early 1920's and middle 1930's which with the appropriate dividend yield would have implied expected returns as low as −22 percent. As long as cash is available, no investor if he really held this belief would hold stock. Using 10 years of prior data yielded negative estimates of the expected market return in only a few cases and then only with the geometric.

[35] This range is consistent with that found in a survey of stockholders by W. G. Lewellen, R. C. Lease, and G. C. Schlarbaum.

TABLE 7—"EXPECTED" ANNUAL RATES OF RETURN FOR COMMON STOCKS AND BONDS
1902–71

Period	High Grade Corporate Bonds Yields to Maturity	New York Stock Exchange Composite Stocks		Calculated Market Price of Risk for Stocks Using

[a] The Arithmetic Estimate is the arithmetic mean of annual expected returns where the expected return for the t-th year is taken to be $i_t = D_t/P_t + GE_t$, where GE_t = arithmetic mean of previous 10 years of earnings growth. Dividends yields were obtained and earnings growth rates calculated from Standard and Poor's Quarterly "Earnings, Dividends and Price Earnings Ratios."

[b] The Geometric Estimate is the same except that GE_t is the geometric mean of the previous 10 years of earnings growth.

percent. The corresponding probability for the market price of risk based upon geometric rates of growth would be 87 percent.

This section has used several different approaches to estimating the market price of risk. All of these methods indicate that the market price of risk is greater than 1.0. The probabilities attached to this conclusion were assessed and, while not always at the frequently cited 5 percent level of significance, were consistent with a high level of significance. To the extent that there is some independence among the various estimates, the probability that the market price of risk is greater than 1.0 would be considerably larger than those reported for each of the individual estimates.

V. The Synthesis

The empirical results in Section III indicate that the assumption of constant proportional risk aversion for households is a fairly accurate description of the market place. More specifically, the study found that with a plausible treatment of investment in homes the net worth of a household had little value in explaining the level of its coefficient of relative risk aversion. Before taking account of potential biases, there was a slight tendency of this coefficient to increase with net worth. After adjusting for the biases, little such tendency remained.[36]

The main exception to this finding of constant proportional risk aversion occurred in the analysis based upon an extremely narrow definition of wealth which excluded homes, the associated mortgages, and human wealth. In this case, there was evidence of decreasing proportional risk aversion. This tendency would be more pronounced if homes were considered a risk-free asset. Since an investor probably considers the value of his home and at least to some extent his human wealth in formulating his investment decisions, the analyses based upon broader definitions of wealth are more pertinent in assessing how the coefficient of proportional risk aversion varies with net worth.

---

[36] These conclusions do not preclude the possibility that the coefficient of proportional risk aversion varies with socioeconomic factors which are uncorrelated with net worth.

In addition, Section III derived various estimates of the product of the market price of risk and the reciprocal of the coefficient of proportional risk aversion. Regardless of how broadly wealth was defined, the estimate of this product was, with one unimportant exception, always less than 1.0. Though the value obtained depends on the definition of wealth, the product of the market price of risk times the reciprocal of the coefficient of proportional risk aversion appears to be between 0.5 and 0.8.

Coupling this conclusion with an estimate of the market price of risk allows an assessment of the coefficient of relative risk aversion. The evidence in Section IV showed with a high level of significance that the market price of risk is in excess of 1.0. The implication is that the coefficient of relative risk aversion for the typical household is in excess of 1.0—contrary to the properties of the *log* utility function. Since the market price of risk is probably around 2.0 or more, the coefficient of proportional risk aversion is more likely to be in excess of two.[37]

Households, of course, only represent part of the demand for risky marketable assets. The aggregate demand function would have to take into account the impact of other investors such as eleemosynary institutions and financial intermediaries. Regardless of how their utility or, more accurately, decision functions are derived, the fact that the ratios of risky assets to net worth for these institutions are usually less than 1.0 and not uncom-

---

[37] This conclusion is based upon the assumption that the tax rates on all sources of income are the same when in fact tax rates differ. The effect is that the estimates of the coefficients of proportional risk aversion reported in the text are downward biased, although the bias is not large and does not vary much among net worth classes. With differential taxes and not including human wealth, an estimate of $\alpha_k C_k$ would be

$$\frac{(1-t_m)E(r_m)-(1-t_f)r_f}{(1-t_m)^2\sigma_m^2}$$

where t_m is the tax rate on risky liquid assets and t_f the tax rate on risk-free assets. Assuming the same tax rate on both kinds of assets, the estimate of $\alpha_k C_k$ would be given by

$$\frac{E(r_m)-r_f}{(1-t_c)\sigma_m^2}$$

where t_c is a weighted average of t_f and t_m. Noting that $(1-t_m)>(1-t_f)$ and $E(r_m)>r_f$, the following inequality holds

$$\frac{(1-t_c)(1-t_m)}{(1-t_m)^2}E(r_m)-\frac{(1-t_c)(1-t_f)}{(1-t_m)^2}r_f>E(r_m)-r_f$$

Upon dividing by $(1-t_c)\sigma_m^2$, the inequality shows that the estimate of $\alpha_k C_k$ derived under the assumption of the same tax for both kinds of assets is biased downwards.

If human wealth is included and assumed taxed at the same rate t_{hw} as risk-free assets, $\alpha_k C_k$ would be given by the same formula as the first one in the footnote times the quantity

$$\left[(1-h_k)+\frac{h_k}{\alpha_k}\cdot\frac{1-t_f}{1-t_m}\cdot\beta_{hk\cdot m}\right]^{-1}$$

If the same rate is applied to all assets, $\alpha_k C_k$ is given by the second formula times the quantity

$$\left[(1-h_k)+\frac{h_k}{\alpha_k}\cdot\beta_{hk\cdot m}\right]^{1}$$

Since $(1-t_f)<(1-t_m)$, not taking account of differential taxes will result in a downward biased estimate of the second term in the product. Since the first term is subject to the same biases as before, the net effect will be that estimates of C_k which do not adjust for the differential taxes associated with human and risk-free wealth will be downward biased.

Under reasonable estimates of the relevant variables, it can be shown that the assumption that tax rates on all sources of income are the same biases downward the coefficient of proportional risk aversion for the broadest definition of wealth by about 8 percent for the \$10,000–\$100,000 net worth class and by 9 percent for the \$500,000–\$1,000,000 class. These results assume: $E(r_m)=0.10$, $r_f=.05$, and $\sigma_m^2=.025$ for all households; for the low net worth households, $t_f=t_{hw}=.10$, $t_m=.02$ in view of the heavy weight of housing in the marketable risky assets of this group, and $t_c=.08$; and for the high net worth households, $t_f=t_{hw}=.35$, $t_m=.25$ in view of the heavy weight of unincorporated business and the small weight of housing and tax-exempts.

monly considerably less than 1.0 would seem to imply that their coefficients of relative risk aversion would tend to be at least 2.0. If, as is probably correct, the riskiness of institutional portfolios as a whole has remained less than that of households, their coefficients of relative risk aversion would tend to be greater than those of households.

In concluding, it is worthwhile to review some of the more important limitations of the models under which the empirical data were interpreted. Such limitations point the way to further work. First, the model made no adjustment for inflation. The presence of unanticipated inflation would mean that no asset denominated in nominal dollars could be considered risk free. Second, the model, in assuming that the changes in the value of an asset were continuous, could not properly incorporate insurance. Third, the model did not incorporate adequately the unique characteristics of housing. Fourth, the model assumed that an investor made his portfolio choice in a one-period context. Thus, the model, in contrast to a multiperiod model, is not rich enough to capture the possibilities of hedging against future changes in the investment opportunity set.[38] For households, perhaps the most widely available hedges are homes which protect against future changes in the cost of housing.

[38] Merton has developed a theoretical multiperiod model which does incorporate continuous changes in the investment opportunity set. E. F. Fama and J. D. MacBeth have developed some preliminary tests of the economic content of Merton's model. It might be noted that a utility function characterized by constant proportional risk aversion is consistent with myopic behavior so long as investment yields in different periods are serially independent.

An Intergenerational Model of Population Growth

By ASSAF RAZIN AND URI BEN-ZION*

The problem of population growth has been only partially formulated in an intertemporal context. Therefore, a link between population theory and economic growth theory is still missing.[1] This paper attempts to provide such a link by analyzing an intergenerational model of optimum population growth. The model accommodates the idea that decisions on increases in population should consider the new population's quality of life. This concept is elaborated upon in a static framework by Gary Becker and Gregg Lewis, Dennis De Tray and Robert Willis. Other literature on population growth, such as Harold Votey, disregards this consideration altogether.[2] More explicitly, this paper assumes that the utility of each generation is a function of the level of its consumption and the *number* and *utility* of the newly born people. We are thus led to consider the utility of an infinite number of generations. This model differs from Paul Samuelson's intergenerational model of pure consumption in which the utility of each generation depends only on that generation's own consumption.

Recently, Philip Neher (1971) analyzed a model of fertility in primitive economies; it is based on the assumption that parents use children as investments to insure future consumption needs. Neher's analysis focuses entirely on the pension motive for having children;[3] our model assumes that fertility is determined so as to balance the parents' welfare derived from additional children against that derived from the children's quality of life.

We first outline a general model of optimum population growth. In order to discuss explicitly various economic aspects of population, we use a simple case in the analysis. Section I sets up the basic model. Section II analyzes the short-run equilibrium conditions. Section III discusses the long-run equilibrium conditions. Section IV presents an explicit solution for a simple case which yields a constant rate of population growth. Section V explores the effects on population growth of public support for investment in children. Section VI analyzes the relationship between population growth and the value of time. Section VII considers intergenerational transfers and pensions. Section VIII relates the analysis to real world population and policy problems.

I. The Model

Let there be identical individuals; let t be a point in time, and also the name of the generation of people born at t−1. Let L_t be the number of people of generation t. Let c_t be their per capita lifetime consumption, and let U_t be the utility indicator of

[2] See the authors for a critical discussion of the formulation in Votey.

[3] On this subject, see Warren Robinson's criticism and Neher's reply.

their preferences. Each generation lives one period.[4] Thus, L_{t+1} (the number of people of generation t+1) may also be regarded as the number of people born at t. Let $\lambda_t = L_{t+1}/L_t$ be the per capita number of people born at t; let K_t be the total amount of physical capital, and let $k_t = K_t/L_t$ be the per capita amount at t. In general, when U_t is a function of c_t, λ_t, and U_{t+1}, we can write an intergenerational utility indicator $V = U_t(c_t, \lambda_t, U_{t+1}(c_{t+1}, \lambda_{t+1}, U_{t+2}(\ldots)))$, where $t = 0, 1, 2, \ldots$.[5]

A few remarks on the welfare function $V(\ )$ are in order. First, note that in effect the first generation lives forever through its offspring; therefore, our approach is more general than the one adopted by Neher (1971). According to Neher's approach, parents' concern for the future is represented by the utility of consumption enjoyed by their children but only during the children's first period of life. In our model, the concern of parents for their children is not limited at all.

Second, note that since in this paper we use $V(\ )$ as the guide for intergenerational allocation of society's resources, it is only the first generation's welfare that directly enters into the social welfare function.[6]

We assume that preferences are the *same* for each generation and can be represented by an *additive* utility function $U_t(c_t, \lambda_t) + \beta U_{t+1}$; this implies

$$(1) \qquad V = \sum_{t=0}^{\infty} \beta^t U(c_t, \lambda_t)$$

where β is the subjective factor by which the current generation discounts the utility of the next generation.[7] Note the following consistency of the model: under full certainty, the parent generation's plan for future generations' increases in consumption and population is identical with that which the future generations will desire for the given amount of capital they will inherit. This is obviously the result of the specific form of utility function in (1). Let the capital of the next generation be produced according to a linear homogeneous function $F(\cdot)$,[8]

$$(2) \qquad K_{t+1} = F(K_t - C_t, L_t)$$

where $K_t - C_t$ is the total saving. In per capita terms, (2) can be rewritten as:

$$(3) \qquad \lambda_t k_{t+1} = f(k_t - c_t)$$

where $f(k_t - c_t) \equiv F(k_t - c_t, 1)$.

Note that the budget constraint in equation (3) implies that for generation t, the amount of k_t (which is inherited from previous generations and is *given*) can be allocated to two ends: to consumption c_t, or to the amount of resources to be left over to each individual in the next generation k_{t+1}. These quantities vary according to changes in population λ_t. This is analogous to the budget constraint used in Becker and Lewis where λ is regarded as the number of children in a family and k_{t+1} as the amount invested in their "quality."[9]

---

[4] This assumption implies nonoverlapping of generations and therefore excludes basic mechanisms such as loans rather than intergenerational gifts. In Section VII we show that our results carry over to a more general model in which this assumption is relaxed.

[5] The inclusion of population growth in the social utility function also has an empirical implication for the measurement of welfare improvement. Growth of per capita income by itself is an inappropriate measure of welfare improvement, and it is biased against countries with a high rate of population growth.

[6] A more general approach is to define a social welfare function for intergenerational equity which includes as its argument a vector of welfare functions belonging to different generations. This is a complex problem in both its conceptual and analytical aspects, and lies beyond the scope of the paper. Our approach should be regarded as a first attempt in this area.

[7] In particular, note that the rate of discount is constant. Allowing in the model for a variable rate of discount will not change any qualitative results of the paper.

[8] The reader may refer to Nissan Liviatan for an analysis of optimum economic growth which utilizes the discrete-time formulation.

[9] In the model, the inherited capital may include both human and nonhuman capital (when they are regarded as perfectly substitutable in production).

The decision problem of the current generation can now be written as:

$$V(k_0) = \max \sum_{t=0}^{\infty} \beta^t U(c_t, \lambda_t) \tag{4}$$

$$0 \leq c_t \leq k_t; \qquad 0 \leq \lambda_t \leq \bar{\lambda}$$

subject to (3) and a given level of k_0 where $\bar{\lambda}$ is the maximum feasible level of population growth. Marginal utilities are positive and diminishing.[10]

We can now provide the following characterization of an interior solution of (4).

$$\frac{\partial U}{\partial \lambda}(c_t, \lambda_t) = \frac{\beta}{\lambda_t} k_{t+1} \frac{\partial U}{\partial c}(c_{t+1}, \lambda_{t+1}) \tag{5}$$

$$\frac{\partial U}{\partial c}(c_t, \lambda_t) = \frac{\beta}{\lambda_t} \frac{\partial f}{\partial k}(k_t - c_t) \frac{\partial U}{\partial c}(c_{t+1}, \lambda_{t+1}) \tag{6}$$

Equation (5) may be interpreted as describing the optimum decision with respect to the level of population growth λ_t. On one hand, an extra unit of λ_t will increase welfare by the marginal utility of population growth, the left-hand side of (5). On the other hand, from (3), for given values of k_t and c_t, this increase in λ_t will reduce the next generation's per capita capital k_{t+1} by the amount of k_{t+1}/λ_t; this entails a loss for the next generation of (k_{t+1}/λ_t) times the marginal utility of consumption. This utility loss (discounted by β) appears on the right-hand side of (5). In equilibrium, according to equation (5), the gain and the loss in utility are equated.

Equation (6) may be interpreted as describing the optimizing level of consumption c_t. On one hand, an extra unit of c_t will increase utility by the marginal utility of consumption, the left-hand side of (6). On the other hand, this entails a reduction in the next generation's capital; this loss is expressed in utility terms by the right-hand side of (6).

II. The Short Run

In the short run, when the initial value of k is given, the system of equations (3), (5), and (6) may be solved for the quantities of the three "goods": current consumption c_0, population growth λ_0, and next-generation capital k_1 (all expressed in per capita terms). The term k_1 does not appear directly in the utility function and thus is not an ordinary good; we must use its imputed value. Since at equilibrium an extra unit of capital can be used either for consumption or for saving with equal marginal gain (equation (6)), we have[11]

$$\frac{\partial V(k_t)}{\partial k} = \frac{\partial U(c_t, \lambda_t)}{\partial c} \tag{7}$$

Equation (7), specialized for t = 1, will yield the imputed value of the next-generation capital k_1.

Figures 1 and 2 represent a short-run interior solution, where marginal rates of substitution and marginal rates of transformation between the three goods are equalized. At point B in Figure 1, the marginal rate of substitution between λ and k_1

$$\frac{\partial U(c, \lambda)}{\partial \lambda} \bigg/ \beta \frac{\partial V(k_1)}{\partial k}$$

is equal to k_1/λ, the marginal rate of transformation between λ and k_1. This condition can be derived by substitution of (7) into (5). As shown in Figure 1, a necessary condition for an interior solution for λ and k_1 is that the slope of the indifference curve diminishes faster than the slope of the

---

[10] In the real world one may conceive of situations where the marginal utility of a child is nonpositive. For example, in a cooperative system such as the Israeli kibbutz where parents do not directly bear the cost of raising their children, parents may reach a point of saturation. We can reinterpret $\bar{\lambda}$ as the level of λ where $\partial U/\partial \lambda = 0$.

[11] It can be shown that $V(k)$ is concave, i.e., $\partial^2 V/\partial k^2 > 0$.

transformation curve as λ increases. This implies the following condition:[12]

$$(8)\quad \left(\frac{\lambda U_{\lambda\lambda}(c,\lambda)}{U_\lambda(c,\lambda)}+1\right)+\left(\frac{k_1 V_{kk}(k_1)}{V_k(k_1)}+1\right)<0$$

where U_λ, V_k, $U_{\lambda\lambda}$, and V_{kk} are first- and second-order partial derivatives.

At point C in Figure 2, the marginal rates of substitution and transformation between c and λ—given respectively by $[\partial U(c,\lambda)/\partial c]/[\partial U(c,\lambda)/\partial\lambda]$ and $f'(k_t - c)/k_1$—are equalized. This condition can be derived from equations (5) and (6). In general, not all three "goods" (c, λ, and k_1) need be normal. In the diagrams we observe different cross-sections of a three-dimensional diagram; therefore when k_0 is increased, there are shifts in both indifference and transformation curves in Figures 1 and 2, so that the expansion paths need not be upward sloping and the increase in k_0 may result in a decline in the quantity of one or two of these goods.

FIGURE 2

Putting this differently, in the budget constraint (3), either λ or k_1 may be regarded as a price of the other. In the event that k_0 increases and λ and k_1 change, the wealth effect is mixed with the price effect. As a result, the direction of change in the quantities of all subsets of the three goods is not known a priori. This point was elaborated upon by Becker and Lewis in the context of their model.

III. The Long Run

At steady states (when they exist), the system of equations (3), (5), and (6) reduces to:

$$(9)\qquad \lambda k - f(k - c) = 0$$

$$(10)\qquad \lambda U_\lambda(c,\lambda) - \beta k U_c(c,\lambda) = 0$$

$$(11)\qquad \lambda/\beta - f'(k - c) = 0$$

where $U_\lambda = \partial U/\partial\lambda$, $U_c = \partial U/\partial c$.

Equation (11) may be interpreted as the "modified Golden Rule," where the marginal productivity of capital $f' - 1$ is equal to the rate of population growth n plus the subjective rate of discount δ.[13]

One remarkable property of the steady state is that it is invariant to shifts in utility which keep constant the marginal rate of substitution between population growth and consumption U_λ/U_c. Therefore, the steady-state equilibrium (but not the path converging to it) results from an *ordinal* utility (with a given discount factor β) since any monotone increasing transformation of $U(\ )$ leaves the steady state unchanged.

---

[12] Note that one of the cases in which an interior equilibrium is not achieved is when the utility function is logarithmic, i.e., $U(c, \lambda) = a\ log\ c + b\ log\ \lambda$. In this case, the marginal rate of substitution between k_1 and λ is $a\lambda/\beta b k_1$, while the marginal rate of transformation is λ/k_1. For example, equality is achieved if $a = \beta b$, but then the indifference curve coincides with the transformation curve, leaving the values k_1 and λ indeterminate. Otherwise, i.e., when $(a \neq b\beta)$, a solution may not exist. To see this, consider a two-period model with $V = a\ log\ c_0 + b\ log\ \lambda_0 + \beta\ log\ k_1$. We can rewrite this as $V = a\ log\ c_0 + \beta\ log\ (\lambda_0 k_1) + (b - \beta)\ log\ \lambda_0$. The product $\lambda_0 k_1$ as such appears explicitly in the budget constraint $\lambda_0 k_1 = f(k_0 - c_0)$; thus, when $b - \beta < 0$, λ_0 may be regarded as a free good with a negative marginal utility. However, $\lambda_0 = 0$ is not a solution. Therefore, a solution does not exist.

[13] Note that $\lambda = 1 + n$, $\beta = 1/(1+\delta)$. Therefore, $f' - 1 = (\lambda/\beta) - 1 = (1+n)(1+\delta) - 1 \approx \delta + n$.

IV. The Constant Rate of Population Growth

Since it is difficult to further characterize the general solution, it may be instructive to consider a simple case. We believe that the analysis of this case enables one to understand the essential characteristics of the model, and that it can be used to make inferences in more general situations.

Let the utility function be given by:

$$U(c, \lambda) = a \log c + v(\lambda) \tag{12}$$

where a is a positive number and $v(\lambda)$ is the utility arising from population increase with positive and diminishing marginal utility. In order to guarantee an interior solution, we assume that the elasticity of the marginal utility of population increase is greater than one (i.e., $-\lambda v_{\lambda\lambda}/v_{\lambda} > 1$).

Let the production function be of a Cobb-Douglas form

$$f(k - c) = r(k - c)^{\alpha} \tag{13}$$

where the constants r and α are positive and $\alpha \leq 1$. The intertemporal utility function which is obtained upon substituting (12) into (1) has two special properties. First, the marginal rate of substitution between consumptions at different points of time is not affected by population increases. Second, the elasticity of substitution between consumptions at different points of time is unitary. It turns out that these are the factors which determine in the following analysis the particular results. However, it seems to us that the functions of consumption and population growth which are derived from (12) and (13) are not necessarily inconsistent with those observed in the real world.

Substituting (12) and (13) into (6), we find a solution:

$$c_t = (1 - \alpha\beta)k_t \tag{14}$$

Substitution of (14) into (3) and (5) yields

$$\lambda_t k_{t+1} = r(\alpha\beta)^{\alpha} k_t^{\alpha} \tag{15}$$

$$\lambda_t v_{\lambda}(\lambda_t) = \frac{a\beta}{1 - \alpha\beta} \longrightarrow \lambda = \lambda^* \tag{16}$$

We therefore obtain a consumption function with a unitary-income elasticity (equation (14)) and a constant rate of population growth λ^* (equation (16)). The next-generation capital stock will increase as current resources increase (equation (15)).

Solving the difference equation (15) for $\log k_t$ using (14) and (16), we get

$$\log k_t = \log\left[r(\alpha\beta)^{\alpha}/\lambda^*\right] \cdot \left[\frac{1 - \alpha^{t+1}}{1 - \alpha}\right] + \alpha^t \log k_0 \tag{17}$$

Equations (14), (16), and (17) yield a complete short-run solution for our problem. The comparative statics properties of the short-run solution are straightforward. For example, an increase in the discount rate of the utility of future generations will increase the present consumption and the number of children which are undiscounted in the utility of the present generation; it will also reduce the capital per child which affects the utility function only indirectly through the effect on the utility of the next generation. If individuals are risk averters an increase in the intergenerational discount factor may result from increases in uncertainty regarding the continuity of the family, namely, uncertainty associated with the length of the horizon of the extended family.[14] Also, it is seen from (16) that an increase in the capital productivity parameter α will increase intergenerational accumulation of capital and lower the rate of population growth.

---

[14] For a detailed analysis of uncertainty regarding the horizon of the decision-making unit, see Menachem Yaari.

Turning to the long run, for values of α below unity we have a stable equilibrium k^* (as $t \to \infty$),

$$k^* = [r(\alpha\beta)^\alpha/\lambda^*]\, 1/(1-\alpha) \tag{18}$$

V. Public Support for Investment in Children and Population Growth

One characteristic of the modern state is the existence of subsidies for the education of the young generation, paid by taxes imposed on the parent generation. From the individual parent's point of view, there is no necessary relationship between the subsidies (which are received on a per child basis) and tax payments (which are paid on the basis of the parents' income). The model of Section IV is now viewed as describing the behavior of a typical (extended) family. We analyze the effect of government policy on population growth by using this model.

Subsidies for the investment in children born at t can be represented by a proportional increase in the amount of capital invested in a child, k_{t+1}. Equation (3) can therefore be rewritten as

$$\lambda_t k_{t+1} = (1+s) f(k_t - c_t) \tag{19}$$

where s is the rate of the subsidy.

Assume that the public subsidy is financed by a proportional tax τ, so that the disposable wealth at point t is $k_t(1-\tau)$. In order for the government's budget to be balanced over the infinite horizon and for the government spending not to exceed its revenue at any point in time, we need

$$\sum_{t=0}^{T} \lambda_t k_{t+1} s \leq \sum_{t=0}^{T} \tau k_t, \qquad \text{for } T = 1, 2, \ldots \tag{20}$$

We assume that the tax-cum-subsidy policy, when enacted, is expected by individuals to last forever. What is the effect of once-and-for-all changes in the rate of subsidy, with a balanced government budget, on population growth? In the presence of the tax-cum-subsidy policy, equations (5) and (6) are modified as follows.

$$U_\lambda(c_t, \lambda_t) = \frac{\beta}{\lambda_t}(1-\tau) k_{t+1} U_c(c_{t+1}, \lambda_{t+1}) \tag{5'}$$

$$U_c(c_t, \lambda_t) = \frac{\beta}{\lambda_t} f'((1-\tau)k_t - c_t) \cdot (1+s) U_c(c_{t+1}, \lambda_{t+1}) \tag{6'}$$

In the special case considered in Section IV, these equations can be solved explicitly to get

$$c_t = (1-\tau-\alpha\beta) k_t \tag{21}$$

$$\lambda_t v_t(\lambda_t) = \frac{(1-\tau)\alpha\beta}{1-\tau-\alpha\beta} \to \lambda_t = \lambda^*(\tau) \tag{22}$$

$$log\, k_t = log\,[r(1+s)(\alpha\beta)^\alpha/\lambda^*(\tau)] \cdot \frac{1-\alpha^{t+1}}{1-\alpha} + \alpha^t log\,(1-\tau)k_0 \tag{23}$$

where s and τ are chosen so as to satisfy (20).

From equation (21) it can be inferred that consumption is negatively related to the rate of the income tax τ, whereas it is unaffected by the subsidy. Since the elasticity of the marginal utility of population increase is assumed to exceed one,[15] and the term on the right-hand side of (22) is positively related to τ, an increase in the tax rate τ lowers the rate of population growth λ, whereas the rate of population growth is not affected by the subsidy. It is the Hicks-neutral nature of the subsidy that is the reason for the insensitivity of both λ and c to changes in the subsidy rate. Putting this somewhat differently, absolute prices of λ and c in all periods change by the same proportion leaving relative prices unchanged, thus creating no incentives for changes in these variables.

---

[15] See the discussion in Section IV.

The model thus implies that an increase in the subsidy to the next generation's capital which is financed by an increase in the rate of income tax will lead, as expected, to lower levels of consumption and population growth and to an increase in the rate of capital accumulation.

VI. Population Growth and the Value of Time

The model of the preceding sections did not capture one important aspect of the population problem, namely, the effect of changes in the value of time on the optimal policy with regard to population increase. In this section, time requirements for raising children are explicitly introduced. Population increases will imply reductions in the amount of time devoted to productive purposes.

Let g denote the *fraction* of the lifetime of the parents' generation devoted to raising children, which is assumed to be an increasing function of the number of children per family.[16] Inverting this relationship, the number of children per family λ_t is an increasing function $\phi(\ )$ of the fraction of time which the parents' generation devotes to raising children g_t.

$$\lambda_t = \phi(g_t), \quad \phi'(\ ) > 0 \tag{24}$$

The total time devoted by the parents' generation to productive activities is $(1-g_t)L_t$. This new element will require the following modifications in the equations of Section I:

$$\lambda_t k_{t+1} = (1 - g_t) f\left(\frac{k_t - c_t}{1 - g_t}\right) \tag{25}$$

$$U_\lambda(c_t, \lambda_t) = \beta \frac{k_{t+1}}{\lambda_t} U_c(c_{t+1}, \lambda_{t+1}) + \frac{\beta F_L}{\phi'(g_t)\lambda_t} U_c(c_{t+1}, \lambda_{t+1}) \tag{26}$$

where $F_L = f - (k-c)/(1-g)f'$ is the marginal productivity of labor.

Equation (26) differs from equation (5) by having an additional term on its right-hand side. This term corresponds to the cost of time associated with the population increase. One extra unit of λ requires an increase of the magnitude $1/\phi'(g)$ in g (see (24)). The resulting decrease in labor force participation will lower the per capita production of capital of the next generation according to the marginal productivity of labor divided by the rate of population growth F_L/λ. The utility value of the loss viewed by the present generation is $\beta F_L U_c/\lambda\phi'$. It is instructive to solve this model explicitly in the special case considered in Section IV. The modification of the solution in Section IV is in equation (16) which determines the rate of population growth λ while equation (14) is unaffected. We get

$$\phi(g_t) v_\lambda(\phi(g_t)) = \frac{a\beta}{1 - \alpha\beta} + a\beta \frac{1 - \alpha}{1 - \alpha\beta} \frac{\phi(g_t)}{\phi'(g_t)} \longrightarrow g_t = g^* \tag{27}$$

Equation (27) implies a *constant* fraction of time g^* to be devoted to raising children. This implies, in view of (24), a *constant* rate of population growth.

The reader may recall that the model assumed constant returns to time invested in raising children. A straightforward implication of the analysis is that if the function relating the number of children to total time devoted to raising children exhibits increasing (diminishing) returns to scale, the rate of population growth will increase (decrease) with the capital-labor ratio.

This model suggests that in relation to population growth, it is misleading to measure the value of time by the marginal productivity of labor as such. The marginal productivity of labor varies over time, together with the capital stock (except at a steady state). The factor which does *not* vary with the capital stock in this special case (and hence does not vary over time) is the *utility value of time:* $U_c F_L$. This is so since a proportional increase in the capital stock will lead to an equiproportionate increase in the consumption of the next generation, and, as a result, to an equiproportionate decrease in its marginal utility. Also, the marginal productivity of labor goes up by the same proportion. This leaves both the value of time $U_c F_L$ and the rate of population growth λ unchanged. In general, however, the value of time which determines, among other things, the rate of population growth might move either with or in opposition to the capital stock.[17] In particular, development of the economy over time (associated with the accumulation of capital) need not imply an increasing time trend for the utility value of time.[18]

---

[16] This can be interpreted as maternity costs. Investment in the human capital of children can be introduced in a similar way.

VII. Intergenerational Transfers and Pensions

In previous Sections I–III the model assumed no overlapping of generations, in the sense that parents were not alive during their children's productive time. In this section we relax this assumption in order to accommodate basic mechanisms such as intergenerational loans, which parents can utilize to delay consumption from productive to nonproductive periods; this is in addition to intergenerational transfers which were considered previously. While this approach is in line with that of Neher (1971), there are two major differences. First, in the model considered by Neher, children are the sole means of income transfer and pension. In our model, there exists a durable good by which parents' saving can be transferred from one period to another. Second, Neher imposes the restriction that total product is equally shared by productive and nonproductive people. In our model, the distribution of the total product between generations is endogenous.

Consider the family unit at a point in time t composed of three generations; the productive parents generation and the children, denoted by superscript 1; and the old generation who have retired and perform no economic functions, denoted by superscript 2. Generalizing the simple model of the previous sections, at time t parents choose the number of children λ_t, current consumption for its members and children c_t^1, the parents' next period consumption c_{t+1}^2, and the amount of capital transfer k_{t+1} (expressed in per capita units). The problem is to maximize

$$\sum_0^\infty \beta^t U(c_t^1, c_{t+1}^2, \lambda_t) \tag{28}$$

subject to $\lambda_t k_{t+1} = f(k_t - c_t^1 - c_t^2/\lambda_{t-1})$

The first-order conditions are

$$\frac{\partial U}{\partial c^1}(c_t^1, c_{t+1}^2, \lambda_t) = f'(k_t - c_t^1 - c_t^2/\lambda_{t-1}) \frac{\partial U}{\partial c^2}(c_t^1, c_{t+1}^2, \lambda_t) \tag{29}$$

$$\frac{\partial U}{\partial c^1}(c_t^1, c_{t+1}^2, \lambda_t) = (\beta/\lambda_t) f'(k_t - c_t^1 - c_t^2/\lambda_{t-1}) \cdot \frac{\partial U}{\partial c^1}(c_{t+1}^1, c_{t+2}^2, \lambda_{t+1}) \tag{30}$$

---

[17] Correspondingly, its partial effect on population growth is negative or positive.

[18] This is analogous to the effect of changes in the wage rate on labor-leisure choice for an individual consumer. Changes in the wage rate have both substitution and income effects. Similarly, in our model, changes in the capital-labor ratio will have substitution and income effects on population and consumption. While the substitution effect is negative the full effect of capital-labor ratio on population growth is not known a priori. The negative effect on fertility caused by the change in the value of time of mothers which is discussed in Schultz, should be regarded mainly as a substitution effect.

$$\lambda_t \frac{\partial U}{\partial \lambda}(\overset{1}{c}_t, \overset{2}{c}_{t+1}, \lambda_t) = \frac{\partial U}{\partial c^2}(\overset{1}{c}_t, \overset{2}{c}_{t+1}, \lambda_t) \cdot [f(k_t - \overset{1}{c}_t - \overset{2}{c}_t/\lambda_{t-1}) - \overset{2}{c}_{t+1}] \tag{31}$$

Consider again a simple case

$$U(\overset{1}{c}_t, \overset{2}{c}_{t+1}, \lambda_t) = a \log \overset{1}{c}_t + b \log \overset{2}{c}_{t+1} + v(\lambda_t) \tag{32}$$

$$f(k_t - \overset{1}{c}_t - \overset{2}{c}_t/\lambda_{t-1}) = r(k_t - \overset{1}{c}_t - \overset{2}{c}_t/\lambda_{t-1})^{\alpha}$$

where b/a can be regarded as the intrageneration discount factor. Substituting (32) into (29)–(31) we can solve for the desired level of consumption and population. This is given in (33).

$$\begin{aligned} \overset{1}{c}_t &= m(k_t - \overset{2}{c}_t/\lambda_{t-1}) \\ \overset{2}{c}_{t+1} &= p k_{t+1} \lambda_t \\ \lambda_t v'(\lambda_t) &= b \frac{1-p}{p} \end{aligned} \tag{33}$$

where $m = 1 - \alpha(a\beta + b)/\beta(a + \alpha b)$

$p = b(1 - \alpha\beta)/(a\beta + b)$

The consumption functions in (33) have unitary income elasticities and population growth λ_t is *constant*. From (33), pension per family of the old (nonproductive) generation t, c^2_{t+1}, can be written as follows.

$$\overset{2}{c}_{t+1} = \lambda_t pr(k_t - \overset{2}{c}_t/\lambda_{t-1})^{\alpha}(1 - m)^{\alpha} \tag{34}$$

It can be seen from (34) that the pension is an increasing function of the rate of population growth λ_t, and the amount of saving made in the previous period by the now nonproductive generation, $(1-m) \cdot (k_t - c^2_t/\lambda_{t-1})$. Thus, the pension of the nonproductive generation is determined by the number of productive families and by the amount of transfers made by such a family. The major difference between Neher's results and ours pertains to the latter.

In Neher's model the portion of saving of a productive family that is received by nonproductive families depends on a given distributional rule. In this model it is affected by savings in the previous period of the nonproductive generation. In the model we do not specify the mechanism which determines the share of output received by the nonproductive generation. In particular, this income need not take the form of an intergenerational gift; in fact, it can consist of interest payments on intergenerational loans and returns to ownership of physical capital.[19] For simplicity the model did not consider the possibility of children caring for their parents. Obviously, this factor by itself will increase pensions.

VIII. Conclusion and Implications

The model has a few implications for real world problems which we now wish to emphasize. First, the increase in capital productivity tends to increase intergenerational accumulation of capital and to lower the rate of population growth. This may be a result of capital-biased technological change.[20]

Second, we discuss a government program of subsidizing investment in children's future well-being, financed by income tax. Specifically, the type of subsidy considered is such that government shares with parents the investment in children. Obviously, parents can use a subsidy either to increase the investment per child with a given number of children, or to increase the number of children with a given amount invested in a child, or a combination of the two. The analysis suggests that the subsidy by itself will tend to increase investment in a child, and has a weaker effect on the number of children. However, the effect of the system of subsidies financed by taxes is to reduce the rate of population growth as well as the level of consumption, thereby increasing capital (per capita) of the next generations.

---

[19] It may also be noted that if there are preferences as to the form of the pension income, it may affect the allocation of investment between human and nonhuman capital.

[20] The transfer of technology from developed to underdeveloped countries through technical assistance may lead to technical change of this kind.

Third, we show that as long as time requirements of raising a child are given, the increase in capital per worker (which in turn raises real wages) has no clear effect on the rate of population growth since it involves both income and substitution effects. The same holds true for Hicks-neutral technical change. However, the partial effect of labor-biased technical change which raises the utility value of time is to lower the rate of population growth. Obviously, if technical change is associated with a reduction in the time requirement of raising children, it will have a positive effect on population growth. Also, we show that in the case of economies of scale in raising children, the rate of population growth is positively related to the level of capital per worker; it is negatively related to the level of capital per worker in the case of diminishing returns.[21]

Finally, the case of overlapping generations is incorporated into the model as an extension of the recent contribution by Neher (1971). The extension allows the pension of the nonproductive generation to depend on its savings, in addition to being dependent on the number of its productive offspring. The model implies that the pension of the now nonproductive generation will be positively related to the amount of capital per worker in their productive period, to the productivity of capital, and to the intragenerational and intergenerational discount factors.

The model has also been extended in two additional directions: differences in tastes among generations and uncertain population changes.[22] The main results of these extensions (not presented here) are the following:

Considering the effects of differences in tastes between generations on current decisions regarding consumption and population changes, the analysis suggests that a consumption-oriented trend over generations tends to lower the current rate of population growth in addition to its negative effect on current consumption. This is similar to the effect of a change in the factor by which the utility of future generations is discounted on these variables. Changes in the utility function pertaining directly to children have a weaker effect on current population growth and consumption.

It is shown that increased uncertainty with regard to the continuity of the extended family (which is equivalent to increased intergenerational discount rates) tends to increase the rate of population growth, whereas it lowers the rate of capital accumulation over generations. Another kind of uncertainty in the form of stochastic disturbances to survival rates of new members of the family has a detrimental effect on population growth.

---

[21] Cooperative systems which have economies of scale in raising children, such as the Israeli kibbutz, have relatively greater numbers of children per family for a given level of capital per capita. It is suggested by the model that an increase in capital per worker (over time) will raise the rate of population growth in these systems.

[22] A draft containing the derivations of these results is available on request from the authors.

Search in the Labor Market and the Duration of Unemployment: Some Empirical Evidence

By John M. Barron*

Recently several writers have examined job search behavior by an unemployed worker.[1] In the analysis, the period of time between successive wage offers to an individual has commonly been taken as constant. John McCall, for instance, assumed that an individual invariably obtained one job offer per period. Dale Mortensen (1970b) equivalently assumed a constant probability of receiving a wage offer each period. In this context, job search has been characterized as search for an acceptable wage.[2] The implication is that the expected length of unemployment depends solely on the individual's acceptance (or reservation) wage, optimally chosen, and the existing wage offer distribution.

One aspect of job search heretofore not emphasized is the individual locating a vacancy (wage offer). This element of search is captured below by introducing a random visiting of firms by the job searcher to locate an employment opening.[3] This extension permits presentation of a more complete job search theory which, as Charles Holt (1975) suggests, makes allowance for the time it takes to search firms for vacancies as well as the time it takes to search vacancies for suitable wages. The approach allows explicit consideration of an "involuntary" aspect of search not present in the existing literature.

Section I develops a model of job search by an individual that incorporates the above aspects of search. This model then allows in Section II a fruitful discussion of the elements affecting an individual's acceptance wage and the duration of unemployment. It becomes clear that the expected duration of unemployment entails more than a comparison of an acceptance wage and the wage offer distribution. Indeed, the model makes possible computation of a proxy for the probability that the typical individual engaged in job search will accept a wage offer. It is found that

This research was partially supported by a Baker-Weeks Fellowship provided through the Brookings Institution and a doctoral dissertation grant (No. 91-44-74-39) from the U.S. Department of Labor, Manpower Administration. I am indebted to Herschel Grossman and John Kennan for helpful comments on earlier drafts of this paper. In addition, I benefitted from comments by an anonymous referee. However, the usual disclaimers hold.

[1] For example, see articles by McCall, Mortensen (1970a,b, 1974), Reuben Gronau, Michael Rothschild (1974), and Robert Lucas, Jr. and Edward Prescott. Kenneth Burdett offers an excellent review of several results of such efforts. In addition, Rothschild (1973), focusing on market equilibrium, has provided a survey of "... recent theoretical work characterizing markets whose participants act on the basis of sketchy and incomplete information" (p. 1283).

[2] The analysis considers expected income maximizing behavior by the unemployed job searcher. Some recent models of job search have replaced expected income maximizing behavior with expected utility maximizing behavior in a nontrivial manner (see John Seater or John Danforth). This alternative approach suggests inclusion of such factors as the nonpecuniary aspects of job offers, leisure, consumption, and risk in the individual's optimal search policy.

[3] This job search method of going directly to an employer is the predominant method of job search according to recent surveys (see *Employment and Earnings*).

this variable varies directly with the duration of unemployment. Section III discusses the importance of this finding, particularly as it relates to Phillips curve theory. The conclusions of this paper provide support for the arguments of Donald Parsons, and Robert Barro and Herschel Grossman that question the relevance of emphasizing "employment-acceptance friction" in job search to explain the observed relationship between unemployment and aggregate demand.

I. A Simple Search Model

Consider an economy consisting of n_t firms in which each firm requires various types of labor inputs. For such an economy, examination of a division of the labor market by occupation is possible. Though there would exist within each firm a potential distribution of job opportunities, each firm is assumed to have no more than one vacancy for any one of the q types of labor at any time t. For the economy, the number of vacancies for each of the different types of labor required as inputs is designated by $v_t^1, \ldots, v_t^i, \ldots, v_t^q$. The vacancies are assumed randomly distributed among the n_t firms each period. The total number of vacancies in the economy is denoted by v_t.

Existing in the economy is a stock of unemployed workers, denoted by u_t, who are engaged in job search. Each potential employee is considered to possess a distinct combination of previous experience, skills, and formal education that identifies the particular type of labor for which he (she) is suited. Each searcher may then be said to be correlated with one "occupation." The number unemployed in the ith occupation is denoted by u_t^i.

The job searcher is operating in an environment of uncertainty both with respect to the location of a job for which he is qualified and the specific wage, given a distribution of wages, attached to a particular job. In this setting, one can conceptually distinguish search to find a vacancy from search induced by the inequality between an offer and an acceptance wage.

In one period, an unemployed worker expects to contact k firms. A period is defined such that k is sufficiently small ($k<1$) so that the probability of more than one searcher in the ith occupation contacting the same firm in a given period approaches zero.[4] For the individual, the average time (number of periods) taken to visit one firm is $1/k$. The probability, in a random search procedure, of locating a vacancy on contacting a firm is v_t^i/n_t for the ith occupation in period t. Then, in any period, the probability of finding a vacancy is $v_t^i k/n_t$.[5] To simplify notation, let

$$\theta_t^i = v_t^i k/n_t \tag{1}$$

The expected number of periods before an individual in the ith occupation finds a vacancy is $1/\theta_t^i$.

Let C^i denote the monetary (direct) cost of search per unit of time spent searching for the representative individual in the ith occupation. This cost would include transportation expenses and other expenditures.

Once having found a vacancy, the individual must decide whether to accept the wage offer w_t^i, or continue to search. The optimal rule is characterized by an acceptance (or reservation) wage (see Morris DeGroot 1968, 1970). For the representative individual in the *i*th occupation in period t, let $f^e(w_t^i)$ denote the perceived common density function of each of the observations w^i.[6] Then the expected return from searching for one more period R_t^i is given by

---

[4] A similar assumption, in a different context, is made by Gronau. Alternatively, the same result would follow from the assumption that u_t^i is sufficiently small relative to n_t.

[5] Holt suggests that search "proceeds from more promising areas of search to successively less promising ones" (1970, p. 228). This idea has been used by S. C. Salop in part to explain declining acceptance wages. *Ex ante* information about firms and the corresponding systematic job search could be characterized in our model by a falling rather than constant θ_t^i for an individual. The present analysis abstracts from such an effect.

$$R_t^i = \theta_t^i H^i \int_{a_t^i}^{\infty} (w_t^i - a_t^i) f^e(w_t^i) dw_t^i \tag{2}$$

where a_t^i is the acceptance wage of the representative individual and H^i is the expected length of employment in the next job. The searcher stops when he receives a wage offer at least as large as a_t^i, where a_t^i is the unique solution of the equation:[7]

$$C^i = R_t^i \tag{3}$$

That is, the acceptance wage is chosen to equate the marginal cost of searching for one more period C^i, with the expected marginal return from continued search R_t^i. In turn, R_t^i consists of the expected gain on locating another wage offer times the probability of locating a wage offer in the next period θ_t^i.

Note that the above analysis includes no discounting. Consider the case of an infinite time horizon but a positive time discount rate s. Then the cost of continued search includes the value of time as an important element in addition to monetary outlays.[8] In particular, equation (3) becomes

$$C^i + a_t^i = \theta_t^i (1/s) \int_{a_t^i}^{\infty} (w_t^i - a_t^i) f^e(w_t^i) dw_t^i \tag{4}$$

The right side of equation (4) represents the discounted expected return from searching for one more period. The left side of (4) is the cost of continued search which now includes foregone income. As before, the acceptance wage a_t^i is chosen to satisfy equation (4). The cost of continued search may be further altered to the extent that unemployment compensation is available or to the extent that search activity is considered by the individual to be different from work activity.

From equation (3) or (4) it can be shown that an increase in H^i, the expected length of employment, or a decrease in the discount rate will increase the acceptance wage of the representative individual by increasing the expected return to search. Similarly, a recognized increase in v_t^i, the number of vacancies in the *i*th occupation, or k (a measure of search efficiency) will increase the acceptance wage by raising the return to search. A decrease in C^i will increase the acceptance wage of the representative individual in the *i*th occupation a_t^i by decreasing the cost of continued search. A rightward shift in $f^e(w_t^i)$ will also increase a_t^i.

II. The Duration of Unemployment: Empirical Evidence

For the *i*th occupation, the mean probability that a wage offer is accepted, P_t^i, is

$$P_t^i = \int_{a_t^i}^{\infty} f(w_t^i) dw_t^i \tag{5}$$

where $f(w_t^i)$ is the actual wage offer distribution. For the entire economy, the average probability P_t that a searcher accepts a job which he has found is

$$P_t = \sum_{i=1}^{q} (u_t^i / u_t) P_t^i \tag{6}$$

The main interest of this paper is in aggregate phenomena. To simplify aggregation, assume the q occupations to be identical in the variables of interest. Specifically, assume that $P_t^i = P_t$ and that $\theta_t^i = \theta_t = v_t k/n_t q$, where θ_t is the probability of locating a vacancy in period t for the individual. Equivalently, one may consider the *i*th occupation as the representative occupation. As a consequence, the aggregate analysis to follow is the same as an analysis of the *i*th occupation and distributional effects are avoided.

---

[6] In order to avoid unnecessary complications, assume that the individual considers himself knowledgeable of the probability distributions associated with job search. This assumption precludes adaptive behavior arising from search when the distributions are unknown. Rothschild (1974) has examined one case in which the wage offer distribution is unknown.

[7] It is required that the variance of $f^e(w_t^i)$ be finite.

[8] A finite time horizon similarly changes the cost of search per unit time from that formerly proposed. In addition, a finite time horizon implies a declining acceptance wage for an individual engaged in job search (see Gronau).

The importance of determining P_t is that in part it determines the average duration of unemployment D_t, and thereby the unemployment rate U_t of the economy. Robert Flanagan, among others, has shown that in a steady state,

$$U_t = F_t D_t \tag{7}$$

where F_t is the rate of flow of individuals into unemployed status. The model presented in this paper allows examination of the factors involved in determining D_t. Specifically, given θ_t, the probability of locating a vacancy in period t, the average duration of unemployment in the economy is

$$D_t = 1/\theta_t P_t \tag{8}$$

Economic fluctuations are commonly characterized by movements in the number of vacancies. The question of how such a change in v_t affects equation (8) may now be addressed. Assume a fall in the number of vacancies. Consider the effects of such a change on three different parameters involved in determining the average duration of unemployment.

EFFECT 1: According to equation (1), a decrease in v_t increases the expected length of search time to find a vacancy, $1/\theta_t$. Given the average probability of accepting a wage offer P_t, this effect means, by equation (8), a rise in the average duration of unemployment.

EFFECT 2: According to equation (2), a perceived decrease in v_t by decreasing θ_t decreases the expected return from additional search for individuals in each occupation.[9] By equation (3) or (4), this effect means a reduction in acceptance wages. Given a distribution of wage offers, this reduction in acceptance wages implies an increase in P_t (equation (5)), providing to some degree an offsetting force for decreasing the average duration of unemployment.

EFFECT 3: A fall in v_t may be accompanied by a leftward alteration in the distribution of wage offers $f(w_t)$. According to equation (5), to the extent that individuals do not respond by reducing their expectations concerning wage offers $f^e(w_t^i)$, and thereby their acceptance wages, this effect reduces P_t and thus increases the expected duration of unemployment. It is of interest to note that to the extent that individuals fail to recognize a reduction in the number of vacancies as well as in the wage offer distribution, then it is more likely that Effect 3 will dominate Effect 2 regarding P_t.

An explicit expression of the net change in the average duration of unemployment D_t, due to a change in the number of vacancies using either equation (3) or (4) is provided in the Appendix. The net change refers only to the first two effects mentioned above. However, the sign of this expression is unclear. Fortunately, it is possible using existing data to obtain a measure of the effect changes in v_t have on both P_t and D_t. The method for computing D_t and P_t follows.

The probability that, in a given period, the representative unemployed individual in the economy finds and accepts employment is $\theta_t P_t$.[10] The distribution of the number of periods before employment occurs is geometric of the form.

---

[9] Since $1/\theta_t$ is the expected number of periods it takes to locate a vacancy, a reduction in v_t may equivalently be interpreted (by transposing θ_t to the left side of equation (3) or (4)) as increasing the expected cost of search for another wage offer.

[10] The analysis abstracts from variations in the rate at which unemployed workers leave the labor force.

$$(9)\quad g(\mathrm{T};\theta_t P_t) = (\theta_t P_t)(1-\theta_t P_t)^{\mathrm{T}-1}\qquad \mathrm{T}=1,2,3,\ldots$$

The probability that employment occurs within the first T periods, $Pr(E \leq \mathrm{T})$, is then

$$(10)\quad Pr(E \leq \mathrm{T}) = \sum_{h=1}^{\mathrm{T}} (\theta_t P_t)(1-\theta_t P_t)^{h-1} = 1-(1-\theta_t P_t)^{\mathrm{T}}$$

There exist data recording the number of people unemployed for different lengths of time. In general, denote G_t^{ab} and $G_{t-\mathrm{T}}^{ab}$ as the number of people who have been unemployed for at least a periods but for not more than b periods at time t and time t−T, respectively. The variables G_t^{ab} and $G_{t-\mathrm{T}}^{ab}$ would have no common elements but would be adjacent in the sense that $b-a=\mathrm{T}$. Let $G_{t+\mathrm{T}}^{bc}$ denote the number unemployed for at least b periods but for not more than c periods at time t+T. If $c-b$ equals $b-a$, then the ratio $G_{t+\mathrm{T}}^{bc}/G_t^{ab}$ corresponds to $1-Pr(E\leq \mathrm{T})$ which by equation (10) equals $(1-\theta_t P_t)^{\mathrm{T}}$. If $c-b$ equals two times $b-a$, then a quadratic equation results of the form

$$(11)\quad G_{t+\mathrm{T}}^{bc} = G_t^{ab}(1-\theta_t P_t)^{\mathrm{T}} + G_{t-\mathrm{T}}^{ab}(1-\theta_t P_t)^{2\mathrm{T}}$$

Solving and rearranging,

$$(12)\quad \theta_t P_t = 1 - \left[\frac{-G_t^{ab}+\left[(G_t^{ab})^2+4G_{t+\mathrm{T}}^{bc}\,G_{t-\mathrm{T}}^{ab}\right]^{1/2}}{2G_{t-\mathrm{T}}^{ab}}\right]^{1/\mathrm{T}} = 1-j(G_{t-\mathrm{T}}^{ab},\,G_t^{ab},\,G_{t+\mathrm{T}}^{bc})$$

The particular case relating various unemployed groups when $c-b=2(b-a)$ is presented in detail above since estimates of the variables G_t^{ab}, $G_{t-\mathrm{T}}^{ab}$, and $G_{t+\mathrm{T}}^{bc}$ in equation (12) can be obtained from data reported in the *Employment and Earnings* publication of the Bureau of Labor Statistics (*BLS*). Specifically, $G_{t-\mathrm{T}}^{ab}$ and G_t^{ab} were approximated by the seasonally adjusted number unemployed less than five weeks in the survey week of months one (t−T) and two (t), respectively. The variable $G_{t+\mathrm{T}}^{bc}$ then was given by the seasonally adjusted number unemployed for at least five weeks but for not more than fourteen weeks in the survey week of month three (t+T); T was set equal to four. Substituting these values into equation (12), an estimate of $\theta_t P_t$ is obtained. The actual estimate of $\theta_t P_t$ is an average about time t. Since $D_t = 1/\theta_t P_t$, equation (12) thus provides the method for computing an estimate of D_t. Figure 2 graphs D_t so computed for the period April 1969 to November 1973.[11]

Figure 1 presents the "mean duration of unemployment" statistic published by the *BLS*, $\underline{D}_t$, to indicate the fact that the computed D_t is less than $\underline{D}_t$, as has been reported elsewhere (see Hyman Kaitz). While the computed D_t measures the expected duration of unemployment for an individual becoming unemployed in period t, $\underline{D}_t$ measures the average time currently unemployed individuals have been searching for employment. Steve Salant has shown that the difference between $\underline{D}_t$, the mean of the "interrupted spell length," and D_t may be explained under the assumption of varying probabilities of accepting a wage offer among individuals. Further, the exact relation between $\underline{D}_t$ and D_t will vary as the distribution of P_t varies among individuals. Another factor influencing $\underline{D}_t$ but not D_t is changing flows of people entering the unemployed state.

The method used to compute P_t follows from equation (12). Given that $\theta_t = v_t k/n_t q$, then

---

[11] The monthly series for $G_{t-\mathrm{T}}^{ab}$, G_t^{ab}, and $G_{t+\mathrm{T}}^{bc}$ used were for the periods of March 1969 to October 1973, April 1969 to November 1973, and May 1969 to December 1973, respectively.

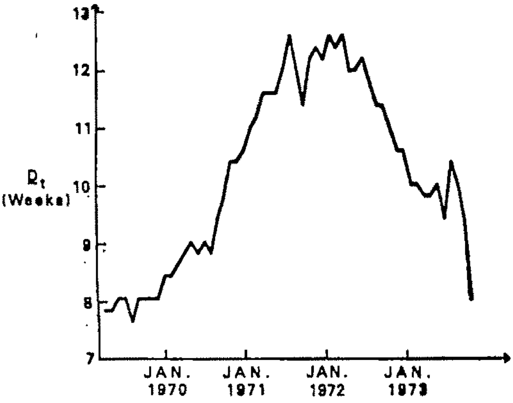

FIGURE 1

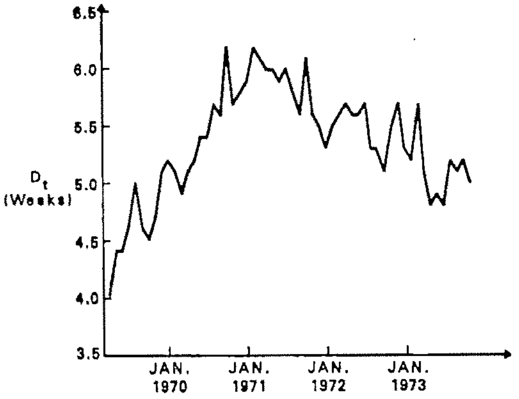

FIGURE 2

$$v_t P_t = (n_t q/k)(1 - j(G^{ab}_{t-T}, G^{ab}_t, G^{bc}_{t+T})) \tag{13}$$

From April 1969 to the end of 1973, data on the seasonally adjusted number of vacancies (in thousands) in *U.S.* manufacturing, v^m_t, have been published by the *BLS*. Figure 3 charts fluctuations in v^m_t for this period. Assume the number of vacancies for the entire economy v_t is some multiple M of v^m_t. Then an expression for P_t is obtained by dividing equation (13) by Mv^m_t. Specifically,

$$P_t = (n_t q/kM) \cdot (1 - j(G^{ab}_{t-T}, G^{ab}_t, G^{bc}_{t+T}))/v^m_t \tag{14}$$

In order to compute a measure of P_t over time, substitute into equation (14) the values of $(1-j(G^{ab}_{t-T}, G^{ab}_t, G^{bc}_{t+T}))$ previously estimated using equation (12), and the values of v^m_t. It was arbitrarily assumed that $n_t q/kM$ equaled two hundred, resulting in arbitrary absolute levels of P_t. However, a different figure for $n_t q/kM$ for the entire period will not alter the observed relative changes in P_t over time which are the data desired. Figure 4 presents the estimated values of P_t for the period April 1969 to November 1973.

A strong assumption in the above analysis is that $n_t q/kM$ is constant over time. The assumed constancy does not mean that in fact n_t (the number of firms), q (the number of occupations), k (a measure of search efficiency), and M (the ratio of the number of vacancies in the economy to the

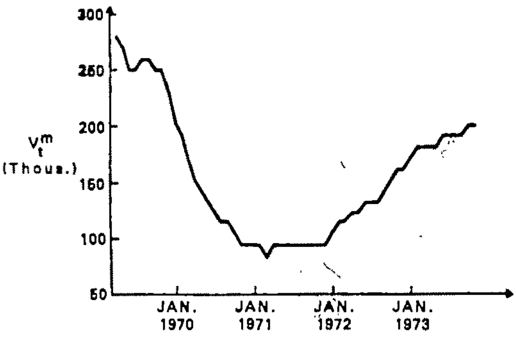

FIGURE 3

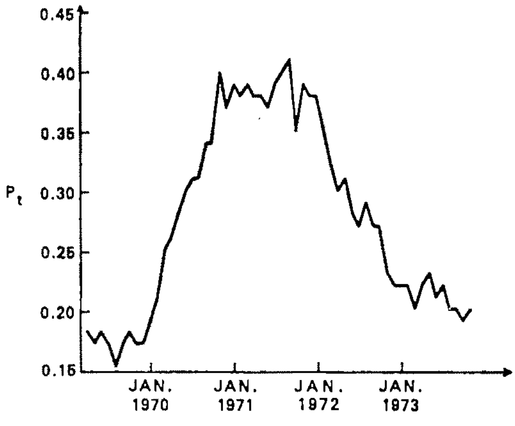

FIGURE 4

number in manufacturing) may not be cyclically sensitive. Rather it reflects the proposition that the net effect of possible cyclical changes in these variables on $n_t q/kM$, though it may bias the reported estimates of P_t, will not alter the observed cyclical pattern of change in P_t.

III. Interpretation of the Analysis and Concluding Remarks

Figures 3 and 4 presented above indicate that a decline in the number of vacancies, by decreasing the expected return to search, increases an individual's probability of accepting a wage offer P_t. This suggests that regarding P_t, Effect 2 (a reduced expected return to search) dominates Effect 3 (an unanticipated fall in the wage offer distribution). Further, Figures 2, 3, and 4 indicate that the average duration of unemployment D_t is inversely related to the number of vacancies but directly related to P_t. These relations suggest that regarding D_t, Effect 1 dominates the net result of Effects 2 and 3 on P_t. This observation also tells us the net effect that a decrease in the frequency of job offers and the resulting increase in P_t has on the unemployment rate. In fact, by equation (7), the unemployment rate rises.[12]

It is of interest to note that for the entire period, P_t seemed to be influenced mainly by the availability of jobs. This result conflicts with the view that workers, specifically unemployed job searchers, react primarily to changes in the actual wage offer distribution relative to their expectations concerning wage offers. For example, according to Mortensen, a falling unemployment rate is due to, in part, " . . . an increase in the actual rate of wage inflation . . . relative to the expected . . . (which) increases the acceptance rate (P_t) because all offers appear to have increased relative to the market average" (1970b, p. 206). Mortensen states that, though temporary, this effect is important. In fact, he suggests that this lag in the adjustment of the rate of expected wage inflation to the actual rate provides an explanation of the short-run Phillips curve. The evidence presented in this paper, however, suggests that a falling unemployment rate coincides with a falling P_t. Thus our analysis casts further " . . . doubt on [those] mechanisms proposed [by, among others, Mortensen] for reconciling Phillips curve phenomena in a price theory framework" (to quote Parsons, p. 398).[13]

To conclude, several qualifications should be cited. First, if one drops the assumption of not more than one vacancy in a particular occupation existing at any firm, this would mean that a halving of the number of vacancies may not double the time required to find a vacancy. Thus, in equation (14) the number of vacancies may enter in the form $(v_t^m)^\beta$ where $\beta < 1$. Secondly, it is likely that the ease of locating a vacancy (i.e., receiving a wage offer) will depend inversely on the number of job searchers. Assuming the number unemployed varies inversely with the number of vacancies, this suggests that in equation (14) the number of vacancies enter in the form $(v_t^m)^\beta$ where $\beta > 1$. The model, by abstracting from the above phenomena, makes the assumption that their net influence will not alter the results substantially.

---

[12] This analysis abstracts from other factors affecting the steady-state unemployment rate which may appear through changes in the variable F_t in equation (7).

[13] Parsons, in examining quit rates, found that if the vacancy rate and relative wages were held fixed then changes in a worker's own wage would not have any systematic effect on quit behavior. Restating, Parsons' evidence concerning quit rates suggests ". . . that wage 'illusion' is not an extremely strong effect" (p. 400). The results of this paper suggest that the unemployed job searcher is similarly not strongly afflicted with wage illusion in determining whether to accept or reject a wage offer. Further, our results are more appropriate for questioning theories of the Phillips curve such as Mortensen's than are Parsons' results. (See Parsons, fn. 23, for more on this.)

APPENDIX

Following is a derivation of the expression for the change in the average duration of unemployment D_t due to a change in the number of vacancies v_t. Assume that $f(w_t)$, the actual distribution of wage offers, equals $f^e(w_t)$, the perceived distribution. Given

$$\text{(A1)} \qquad D_t = 1/\theta_t P_t = \left(\frac{n_t q}{v_t k}\right)\left(\frac{1}{P_t}\right)$$

Then

$$\text{(A2)} \qquad \partial D_t/\partial v_t = -\left(\frac{n_t q}{v^2 k}\right)\left(\frac{1}{P_t}\right) - \left(\frac{n_t q}{v_t k}\right)\left(\frac{\partial P_t/\partial v_t}{P^2}\right)$$

where

$$\text{(A3)} \qquad \partial P_t/\partial v_t = (\partial P_t/\partial a_t)(\partial a_t/\partial v_t)$$

The exact form of equation (A3) depends on whether equation (3) or (4) is considered. From equation (3) we have

$$\text{(A4)} \qquad \partial P_t/\partial v_t = -f(a_t)\,\frac{n_t q}{v^2 k}\,(C)/HP_t$$

Substituting (A4) into (A2), equation (A2) becomes

$$\text{(A5)} \qquad \partial D_t/\partial v_t = (D_t)\left(\frac{1}{v_t}\right)\left(-1 + \frac{f(a_t)(C)D_t}{P_t H}\right)$$

Using equation (4) instead, equation (A3) may be expressed as

$$\text{(A6)} \qquad \partial P_t/\partial v_t = -f(a_t)\,\frac{n_t q}{v_t^2 k}\,(C + a_t) \Bigg/ \left(\frac{P_t}{s} + \frac{1}{\theta_t}\right)$$

Substituting (A6) into (A2),

$$\text{(A7)} \qquad \partial D_t/\partial v_t = \frac{D_t}{v_t}\left(-1 + \frac{f(a_t)(C + a_t)D_t}{P_t/s + 1/\theta_t}\right)$$

Equation (A5) or (A7) may theoretically be either positive or negative in sign. However, empirical evidence suggests that $\partial D_t/\partial v_t < 0$.

Equation (A5) or (A7) may be rearranged to obtain an expression for the vacancy elasticity of the duration of unemployment, denoted E_D. Specifically, for equation (A5)

$$\text{(A8)} \qquad E_D = -\frac{\partial D_t}{\partial v_t}\frac{v_t}{D_t} = \left(1 - \frac{f(a_t)(C)D_t}{P_t H}\right)$$

and for equation (A7)

$$\text{(A9)} \qquad E_D = -\frac{\partial D_t}{\partial v_t}\frac{v_t}{D_t} = \left(1 - \frac{f(a_t)(C + a_t)D_t}{P_t/s + 1/Q_t}\right).$$

Equation (A8) or (A9) and the evidence presented in this paper suggest that $0 < E_D < 1$ (inelastic). The responsiveness of the duration of unemployment to changes in the number of vacancies will depend on the parameters in equation (A8) or (A9) which include among other things, the particular wage offer distribution, the expected length of employment H, and the monetary cost of continued search C.

Private Preference for Collective Goods Revealed Through Voting on Referenda

By ROBERT DEACON AND PERRY SHAPIRO*

When studying consumer preferences or demands for private commodities, researchers have the advantage (at least in principle) of observing the results of individual optimizing decisions in the market. This, of course, is not the case for collectively supplied goods and services. Since the level at which such goods are provided is a collective decision, the observation that an individual with a given income consumes a particular bundle of collective goods is not evidence that this bundle is preferred to all others that are not more expensive.

Empirical studies of the demand for public goods[1] have, in general, examined the relationship between jurisdictional expenditures and various socioeconomic aspects of the constituent populations.[2] These studies typically rely upon a simple concept of political equilibrium in which the actions of a political jurisdiction reflect the desires of the median voter. Utilizing data on median levels of various population characteristics, certain empirical relationships between these characteristics and public expenditures are derived. If the assumptions on the political process are satisfied, these relationships are indicative of median voters' demands.

The problem of estimating individual demands for collective goods may be approached in a second way, by examining voting behavior on referenda related specifically to the provision of public goods.[3] This is the approach taken in the present paper. The presentation begins by developing a model of the individual's voting decision. The problem of using aggregate responses to draw inferences on individual preferences is then addressed and some operational assumptions are employed. Next, the technique of conditional logit analysis is adapted to analyze the categorical voting responses, "yes," "no," and "abstain." Two recent California referenda are used to examine the practical possibility of using voting data to estimate demands for collective goods.

I. The Individual Voting Decision

Under any public policy k an individual i is constrained to consume a vector of collective goods q provided at a collectively chosen level q_k, and faces a total tax liability S_k^i (derived from a system of predetermined tax rates or prices) for the provision of these goods. Within the con-

We wish to acknowledge research assistance from Jeff Newton and helpful comments from Anthony Barkume and an anonymous referee, while retaining full responsibility for any errors which may remain.

[1] The terms "public goods" and "collective goods" are used interchangeably to denote goods and services provided by collective decisions, and do not necessarily imply indivisibilities in consumption.

[2] James Barr and Otto Davis, Thomas Borcherding and Robert Deacon, and Theodore Bergstrom and Robert Goodman provide examples of this approach.

[3] See, for example, Edward Banfield and James Wilson, William Birdsall, and Shapiro.

text of this public policy, the consumer chooses a vector of private commodities $\mathbf{x}^i$ subject to a budget constraint.

$$(1) \qquad (p_k)(\mathbf{x}^i) = I_k^i - S_k^i$$

where p_k is a vector of private goods prices (assumed to be the same for all individuals) and I_k^i is money income. Prices and money income appear with policy subscripts to allow for the very real possibility that they may be influenced, directly or indirectly, by public policy.

Each individual is assumed to have a complete semiorder (see R. Duncan Luce) over all possible bundles of private and collective goods. The concept of a semiorder, while similar to the conventionally assumed preorder, allows for intransitivity in the indifference relation (the reason for introducing such intransitivity becomes apparent below). If P and I denote respectively the relations preferred and indifferent, and if a, b, c are commodity bundles, a semiorder allows for the possibility that aIb, bIc, but aPc. A natural interpretation of this is the notion of threshold levels in individual perception. Luce has shown that the semiorder may be used to induce a weak order on the consumption set and one may then postulate the existence of a utility function U to represent the weak order. While the utility function preserves the weak order, it cannot alone represent the concept of indifference. To capture indifference it is necessary to further define functions δ such that aIb if and only if $-\delta \leq U(a) - U(b) \leq \delta$, where δ takes on the role of a threshold level for utility discrimination. The function δ is defined only in terms of a given utility function so that any monotone increasing transformation of U would require a commensurate transformation of δ to preserve the semiorder.[4]

The individual consumer-voter is assumed to possess a differentiable quasiconcave utility function

$$(2) \qquad U^i = U^i(\mathbf{x}^i, q_k)$$

with vectors of private and collective goods as arguments. Although elements of imprecision have been introduced into individual preferences, it is possible to define the highest level of utility attainable by the individual subject to the budget constraint. Assuming the budget constraint to be satisfied exactly, the solution may be used to solve for the vector of private consumptions in terms of prices, disposable income, and predetermined levels of collective consumption. The highest attainable utility may then be written in indirect form as

$$(3) \qquad \max_{\mathbf{x}^i} U^i(\mathbf{x}^i, q_k) = V^i(q_k, p_k, I_k^i - S_k^i)$$

a function of variables each of which may be affected by the choice of public policy.

Analysis of the individual's role in the collective decision-making process is confined to the act of voting on public referenda. Any proposed change in public policy represents a potential change in one or more of the parameters q_k, p_k, $I_k^i - S_k^i$, which in turn implies a change in V^i. Denoting any two alternatives offered on a ballot by $k=0, 1$, highest attainable utilities under alternative outcomes are

$$(4) \qquad V^i(q_0, p_0, I_0^i - S_0^i) = V_0^i$$

$$(5) \qquad V^i(q_1, p_1, I_1^i - S_1^i) = V_1^i$$

Voters are assumed to cast ballots in their perceived self-interest, i.e., the voting decision is reached by comparing highest attainable utility under the outcomes of alternative policies.

---

[4] Luce defines the "just noticeable differences" δ with respect to individual commodity bundles and allows for the possibility that there may be distinct upper and lower just noticeable differences for any particular commodity bundle. To ease exposition we have assumed that upper and lower just noticeable differences are equal. One unfortunate consequence of this assumption is that it will not, in general, be maintained under monotonic transformation of the utility function. We are indebted to John Howell for this point.

While this specification captures the essence of individual preferences for alternative policy outcomes, the decision to go to the polls at all has been ignored. Most elections offer choices on a variety of issues (public referenda, candidates for political office, etc.). In a general model of voting, the individual would weigh the expected benefit from voting on a range of issues with the costs of going to the polls (time, transportation, etc.), and would not vote at all unless the former exceeded the latter (see Anthony Downs). The aim here is more modest in that the individual's presence at the polls is taken as datum and the decision to vote on a marginal issue is analyzed. If the outcomes of alternative policy proposals were known with certainty and potential utilities could be weighed with knife-edged precision, a simple decision rule would emerge; individual i would vote for alternative 1 if and only if $V_1^i > V_0^i$. Once at the polls the cost of voting on a marginal issue is virtually zero and abstention on a particular issue would occur only in cases of perfect indifference, $V_1^i = V_0^i$. It follows that very few voters would be expected to abstain on any ballot proposition.

In fact, however, one typically observes that a substantial portion of all citizens at the polls will not vote at all on a number of issues. A natural explanation for abstention in the voting booth is provided by the concept of a semiorder and its representation in thresholds for utility discrimination. The decision rule which follows is that the individual will prefer and vote for alternative 1 if highest attainable utility under this outcome is perceptibly greater than attainable utility under alternative 0.[5] If the difference in utility under alternative outcomes is not perceptible, the individual will be indifferent. The following analysis is developed in terms of differences in potential utility under alternative outcomes, which for convenience is written

$$(6)\quad V_1^i - V_0^i = \Delta V^i(q_0, p_0, I_0^i - S_0^i, \Delta q, \Delta p, \Delta I^i - \Delta S^i)$$

where $\Delta q = q_1 - q_0$, etc. Letting x represent the vector of arguments in ΔV^i, (6) may be expressed more compactly as

$$(6')\qquad V_1^i - V_0^i = \Delta V^i(x^i)$$

Designating a vote for 1 as a yes vote, the decision rule becomes: vote yes if $\Delta V^i > \delta^i$; vote no if $\Delta V^i < -\delta^i$; abstain only if $|\Delta V^i| \leq \delta^i$.

While this specification allows for diversity in individual preferences, it does so only through the form of the functions V^i. An operational way to allow for differences in tastes is to assume that such variations are reflected in certain socioeconomic characteristics of the individual. The differences in potential utility then become

$$(7)\qquad \Delta V^i(x^i) = \Delta V(x^i, y^i)$$

where y^i is a vector of individual socioeconomic characteristics.

The term δ^i can be interpreted as a measure of the precision with which an individual is able to distinguish between alternatives. It seems likely that the degree of precision would be related to such factors as the individual's experience, predisposition, and contextual knowledge. Education, for example, might enhance one's ability to discern preference among alternatives, in which case δ^i would be inversely related to educational attainment. To allow for the possibility that these perception thresholds may be influenced by education as well as other socioeconomic characteristics, the specification

---

[5] A variety of alternative reasons for abstention at the polls could be posited. One possibility arises from uncertainty or lack of information on the potential outcomes of policy proposals. Although such uncertainty surely exists, it would not necessarily induce the individual to abstain from making a choice. With most referenda, one potential outcome represents the status quo (e.g., a no vote) which is, presumably, known with relative precision. In such cases, normal risk aversion would not tend to favor abstention, but would, rather, bias the voting choice toward the status quo.

$$\delta^i = \delta(y^i) \tag{8}$$

is adopted.[6]

The model was developed to suggest variables which might influence individual voting decisions, and to facilitate the interpretation of empirical results. It would be impossible (or at least undesirable) to incorporate into the empirical analysis all variables suggested by the model. However, by examining a specific ballot proposal in light of these expressions one may select a subset of the variables which, a priori, appear to be important. For example, a proposed policy change may affect only the jth public good, one private price, and the levels of income of a certain class of citizens. If, further, all citizens initially consume public goods at the same level and face the same private prices, the model can be simplified considerably for purposes of estimation.

II. An Econometric Specification

Since individual ballot choices are not disclosed, only the aggregate responses of groups of individuals are observed. Thus it is necessary to employ several assumptions on the patterns of preferences in voting groups in order to make the model operational. As a first step, let $\bar{z}_m$ and $\bar{y}_m$ denote the vectors of mean attributes and socioeconomic characteristics of members of voting group m. Within the group, assume that ΔV^i is a random variable distributed in a known fashion with mean $\mu(\bar{z}_m, \bar{y}_m)$ and variance σ^2. The distribution of ΔV^i for jurisdiction m is written $g(\Delta V^i | \bar{z}_m, \bar{y}_m)$ and is, therefore, conditional on the vectors of mean attributes.[7] While the means of the distributions will vary across voting groups as mean attributes differ, all distributions are assumed to possess a common variance. Within any voting group characterized by the vectors $\bar{z}_m, \bar{y}_m$, the probability of drawing at random an individual who will vote no (vote for alternative 0) is defined to be

$$P(N | \bar{z}_m, \bar{y}_m) = \int_{-\infty}^{-\delta_m} g(\Delta V^i | \bar{z}_m, \bar{y}_m) d(\Delta V^i) \tag{9}$$

where δ_m is, as yet, unspecified. The probability of drawing a yes vote is

$$P(Y | \bar{z}_m, \bar{y}_m) = \int_{\delta_m}^{\infty} g(\Delta V^i | \bar{z}_m, \bar{y}_m) d(\Delta V^i) \tag{10}$$

and the probability of finding an abstainer is

$$1 - P(N | \bar{z}_m, \bar{y}_m) - P(Y | \bar{z}_m, \bar{y}_m) \tag{11}$$

Although the notation employed is suggestive, the interpretation of δ_m in (9) and (10) is not unambiguous. It has meaning in terms of the individual choice model in Section I only if one adopts the highly restrictive assumption that individual δ^i are identical for all voters in a given jurisdiction m and are a function of the mean socioeconomic characteristics of that group, i.e., $\delta^i = \delta(\bar{y}_m)$. Rather than adopt this

---

[6] Elements of the vector x^i are not included in (8) as they are related to levels of utility, but not to the form of the function.

[7] The reader may feel uneasy with the apparent cardinality in this formulation. Such objections could have been avoided by specifying that individuals impute dollar values to potential policy changes, by defining $R^i = (V_1^i - V_0^i)/\lambda^i$ where λ^i is the individual's marginal utility of income (assumed to be constant with respect to variables influenced by the policy). It can be shown that a first-order approximation to R^i is given by

$$R^i = \sum_j M_j^i \Delta q_j + (\Delta I^i - \Delta S^i - \sum_k x_k^i \Delta p_k)$$

where M_j^i is the individual's marginal rate of substitution between q_j and disposable income. One could then specify a distribution for the R^i. This transformation was not undertaken in the text as it would complicate the presentation with little effect upon the development of the model or interpretation of results.

specification, we merely employ the operating assumption that δ_m is a function of $\bar{y}_m$, and do not directly relate δ_m to individual behavior.

The final tally from jurisdiction m in which T_m citizens voted can be viewed as the outcome of a trinomial experiment performed on a sample of size T_m of the population in the jurisdiction. The observed sample proportions $\hat{P}$ (percent who voted yes or no) are therefore equal to the true probabilities in (9) and (10) plus a random error term. The density functions g in (9) and (10) are taken to be logistic, so that the observed sample proportions are

$$\hat{P}(N_m) = [1+\exp((\delta_m+\mu_m)/\tau)]^{-1} + \epsilon_m^N \tag{12}$$

$$\hat{P}(Y_m) = [1+\exp((\delta_m-\mu_m)/\tau)]^{-1} + \epsilon_m^Y \tag{13}$$

where $\mu_m \equiv \mu(\bar{z}_m, \bar{y}_m)$, $\tau = \sigma\sqrt{3}/\pi$

and the error terms follow a multinomial distribution.

Given the assumed logistic distribution, it is convenient to work with the "logit" transformation

$$\begin{aligned} (12')\quad l(N_m) &\equiv ln\,[\hat{P}(N_m)/(1-\hat{P}(N_m))] \\ &= -(\mu_m+\delta_m)/\tau + \nu_m^N \end{aligned}$$

$$\begin{aligned} (13')\quad l(Y_m) &\equiv ln\,[\hat{P}(Y_m)/(1-\hat{P}(Y_m))] \\ &= (\mu_m-\delta_m)/\tau + \nu_m^Y \end{aligned}$$

where l denotes the logit operator, ln is the natural logarithm, and ν_m^N and ν_m^Y are the transformed error terms.

An estimate of δ_m may be obtained directly by forming the sum

$$l(Y_m) + l(N_m) = -2\delta_m/\tau + \nu_m^R \tag{14}$$

where $\nu_M^R = \nu_m^Y + \nu_m^N$.

For purposes of estimation, the functions $\mu(\cdot)$ and $\delta(\cdot)$ are taken to be linear so that

$$\mu_m/\tau = \bar{z}_m\alpha' + \bar{y}_m\beta' \tag{15}$$

and $\delta_m/\tau = \bar{y}_m\gamma'$

where α, β, and γ are row vectors of constants. Equations (13'), (14), and (15) are combined to yield the following estimating equations

$$l(Y_m) = \bar{z}_m\alpha' + \bar{y}_m(\beta'-\gamma') + \nu_m^Y \tag{16}$$

$$l(Y_m) + l(N_m) = -2\bar{y}_m\gamma' + \nu_m^R \tag{17}$$

The parameters of (16) and (17) were jointly estimated using the minimum logit χ^2 approach (the details of this technique are outlined in J. E. Grizzle et al.).

III. Estimation

While this model provides a concise framework for analysis, the complexities of actual political referenda and data limitations often necessitate the use of less than ideal explanatory variables in empirical analysis. For example, the potential difference in disposable income under alternative outcomes ($\Delta I^i - \Delta S^i$ in (6)) cannot be observed directly. However, it is often reasonable to hypothesize that the incomes of certain segments of the populace (occupational groups, for instance) would be significantly affected by a particular policy. To capture such effects, the proportion of voters in an affected group may be included among the set of explanatory variables. Another type of variable which naturally poses problems for measurement is the level of consumption of various collective goods (q_0 and Δq in (6)). Because these variables are at best difficult to quantify, dummy variables may be used to partition the set of voting aggregates into groups within which collective consumption levels appear to be uniform. The regression coefficients then provide the estimates sought. All of these considerations are explained below in the context of specific referenda.

Two referenda which appeared on recent statewide ballots in California were chosen for analysis. They dealt with conservation of the California coastline and provision of public financing for rapid transit. Both measures elicited a great deal of voter interest and each was concerned explicitly with provision of collective goods. Furthermore, both related to environmental protection.

A. *The Coastal Zone Conservation Act*

The Coastal Zone Conservation Act was submitted to the voters (and adopted) in November 1972. It was an initiative measure designed to create six regional commissions and one statewide commission to oversee development in the California coastal zone. Although the stated purpose of the act was to develop a comprehensive plan for coastal zone land use, the major issues in the campaign hinged upon the power of the regional commissions to prohibit development within the "permit area," a narrow corridor within the coastal zone. The act proposed to preserve the natural coastal environment by halting or delaying development for a period of three years, after which the land use plan would be submitted to the voters for approval. Successful implementation of the act would lead to limiting the rights of some land owners to develop their property. The act was also expected to adversely affect incomes and employment in the construction industry, to delay the siting and construction of new power generating plants, and to have differential impacts upon property values in the affected areas. The measure appropriated a total of $5 million from state funds for three years of operation so that the direct tax burden of the act (exclusive of any effect which changing property values may exert upon local tax bases) was negligible.

The voting aggregates used in the empirical analysis were 334 California cities. Information reported by the California Secretary of State was used to calculate the percentage (as a function of total votes T cast for all presidential candidates), of affirmative Y and negative N votes on Proposition 20 in various cities. Data from the same document were used to compute F, the fraction of votes cast for the Republican or American Independent presidential candidate. Observations on per capita income I, percent of work force employed as laborers or construction craftsmen W, and the mean number of school years completed E in each city were taken from the 1970 U.S. Census. In addition, two partitions of the state were formed. The boundaries of the first partition, $A_1 \ldots A_6$, were drawn so that travel time to the coast was roughly equal from all points within a given zone. The second partition, Q_1, Q_2, and Q_3 divided the state into southern, central, and northern regions, respectively. Dummy variables were defined to identify each city's location in these partitions.

The reason for including income is obvious and, unless the coastal environment is an inferior good, one would expect its coefficient to be positive. The variable W corresponds to ΔI in equation (6) and was included to reflect the potential impact which the policy was expected to have upon incomes in the construction industry: a negative coefficient is expected. The variables E and F correspond to elements of $\bar{y}$ in equations (16) and (17) and were incorporated to capture variations in preference patterns among voters. The dummy variables Q_1, Q_2, Q_3 were employed to reflect differences in the initial condition of the environment. As one moves from south to north (Q_1 to Q_3), the initial quality of the environment becomes higher and, on the basis of a simple diminishing marginal utility argument, one would expect the magnitudes of the coefficients to become progressively smaller. The access zones $A_1 \ldots A_6$ were used to capture differences in the expected change in the level of the collective good (Δq in equation (6)). It was assumed that the expected change in environmental quality was equal for all citizens in the coastal zone (A_1).

However, at locations further inland ($A_2 \ldots A_5$ progressively), individual access to the coastline declines so that any given change in the coastal environment represents a smaller change in the level of environmental quality experienced by the individual.

In terms of the model it was assumed that initial price levels (p_0) and any changes in prices (Δp) expected to follow from the proposed policy (for example, higher future prices for electric power due to delays in expanding generating capacity) were uniform throughout the state. Any price effects would therefore be subsumed in the constant term.

Of all the impacts the policy was expected to have, perhaps the most difficult to sort out empirically involve differential changes in land values. Presumably, owners of undeveloped land in the permit area were faced with a capital loss if the measure was adopted. On the other hand, owners of developed property in the permit area probably stood to gain on balance from the initiative. The data lacked sufficient detail to separate residents of the permit area from those of the coastal zone (i.e., access zone A_1 included cities in both the permit area and the coastal zone). For these reasons, the expected sign of A_1 is ambiguous as it will reflect a combination of accessability and property value effects.

All of the independent variables described above were incorporated in a regression equation to explain $l(Y)$ (see (16)). The socioeconomic characteristics E and F as well as per capita income I, were used as independent variables in estimating (17). Application of the joint estimation technique to this system of equations yielded the estimates displayed in Table 1. Regression coefficients are shown in the first two columns and are interpreted as the overall effects of the independent variables upon the probability of voting in favor of the proposition (col. 1) and the probability of voting on this initiative at all (col. 2). Estimates of α, β, and γ, the items of primary interest, were obtained by linear transformation of the regression coefficients (see equations (16) and (17)) and are reported in columns three and four. These are interpreted as the effects of the independent variables upon expected changes in utility (col. 3) and upon the perception thresholds (col. 4). It is the items in these last two columns which are the subject of discussion below.

In general, the parameter estimates have the expected signs. The income coefficient suggests that the collective good, the natural coastal environment, is normal although the effect is not highly significant. There are, however, considerations which render the interpretation of this item somewhat ambiguous. The nature of the initiative indicated that it would significantly affect property values, particularly in the coastal zone and permit area. The data available did not allow these property value effects to be represented directly and to the extent that property values and incomes are correlated, the income term may be capturing some of these influences. The negative and highly significant coefficient associated with percent laborers corroborates the hypothesis that the initiative was expected to adversely affect incomes and employment in that sector.

The coefficients of locational zones Q_1 and Q_3 (south and north, respectively) also appear quite reasonable. As noted earlier, the initial level of environmental quality was higher in the north than in the south so that a larger coefficient (stronger support) in the south than in the north was anticipated. With regard to the access zones $A_1 \ldots A_4$, none of the coefficients obtained are significantly different from zero (at 5 percent). Although the interpretation of A_1 is unclear for reasons described above, it was expected that the

Sources: Dependent variables and F were formed from data reported in California Secretary of State, *Statement of the Vote*. Variables I, W, and E were obtained from U.S. Bureau of the Census. A description of the dummy variables Q_1, Q_3 and $A_1 \ldots A_4$ is provided in the text.

[a] Standard errors in parentheses.

coefficients of A_2, A_3, A_4 would form a monotonic sequence, as these zones represent progressively smaller changes in the level of the collective good. No such pattern is, however, evident.

The variables E (education) and F (political preference), included to reflect differences in tastes, are highly significant in both equations. Since the issue proposed to usurp some of the traditional rights of property owners, the strong disapproval by voters with relatively conservative political views (as evidenced by the negative coefficient on F in the third column of Table 1) was anticipated. Further, the coefficient of education in that equation lends support to the popular belief that environmental measures are supported by and benefit the better educated segments of society.

Figures in the fourth column of Table 1 relate to the perception thresholds δ. The negative and significant coefficient associated with education is quite plausible as it suggests that the size of perception thresholds (the degree of imprecision in perceiving preference) is inversely related to educational attainment.[8] No a priori hypotheses were formed on the role of political preference and income in the second equation although both terms appear with significant coefficients.

Our inability to measure in any quantitative fashion several of the variables deemed important determinants of the voting choice led to use of proxies for these unquantified influences (for example, the dummy variables $A_1 \dots A_5, Q_1 \dots Q_3$, as well as E and F). To examine the significance of these sets of variables taken as groups, an asymptotic F-statistic was used.[9] The first null hypothesis examined was that the set of coefficients of access zone variables, $A_1 \dots A_4$ is not significantly different from zero. This hypothesis was rejected at 1 percent significance ($F(4,653)=5.7$). The null hypothesis that the coefficients of locational zones Q_1 and Q_3 are not significant, produced an F-statistic of $F(2,653)=3.0$ which coincides with the rejection level at 5 percent significance. The hypotheses that the coefficients of the preference variables E and F are not significantly different from zero in the two equations were clearly rejected at 1 percent ($F(2,653)=140.8$ in the first equation and $F(2,653)=72.1$ in the second equation). General comments and conclusions are reserved for a later section.

---

[8] The reader should keep in mind the previously discussed difficulties associated with interpreting this term.

B. *The Rapid Transit Initiative*

The second issue dealt with public financing of mass transit. By California law, the revenue collected by the state from the tax on gasoline may be used only for public highway purposes. The revenue so collected may be used for the construction and maintenance of state and local roads as well as related administrative and law enforcement activities. Proposition 18, which appeared on the November 1970 ballot (and was rejected by the voters), proposed to amend this law by allowing counties and cities to use up to 25 percent of their share of gas tax revenues for the development of public mass transportation. These revenues could be so used only if specific authorization was approved by a majority of the affected voters. The funds could be used not only to construct and operate new mass transit systems but also to meet interest payments or retire any bonded debt incurred in the construction of such a system. Furthermore, the proposed amendment allowed the state, through legislative fiat, to use an unlimited portion of highway user tax revenues for the control of environmental pollution caused by motor vehicles.

As with Proposition 20, this proposed amendment was viewed in part as an environmental protection measure. By discouraging the use of automobiles and by fostering pollution control research, Proposition 18 intended to help the state ". . . deal with the increasingly grave problem of air pollution"[10] (capitals in the original). In addition to its environmental benefits, the measure was viewed as a way to diminish traffic congestion on the existing freeway system. It was argued that "Each new freeway is loaded to capacity in our urban areas the day it opens, and all the rest of the system becomes increasingly overloaded."[11]

The proposed amendment had one additional feature that was not mentioned by its proponents. If adopted, auto tax revenues could be used not only to finance new construction, but also to retire bonded debt on existing systems. This feature of the amendment made it particularly appealing to the member communities of the San Francisco Bay Area Rapid Transit District (*BART*). The *BART* fixed rail system was considerably more costly than its proponents had originally anticipated, and the system found itself with an unexpectedly large bonded debt. Provisions of Proposition 18 would have allowed *BART* to service its debt without finding new tax revenues.

---

[9] The F-statistic was derived from statistics which are only asymptotically χ^2 and for that reason, their ratio may not converge to an exact F distribution.

[10] See California Secretary of State, "Proposed Amendments to Constitution," *General Election*, Tuesday, Nov. 3, 1970, p. 3.

[11] See fn. 10.

Opponents to Proposition 18 argued that the state needed all the revenues it could obtain to carry out its ambitious freeway master plan. There was a chance not only of diminished state support but also diminished federal matching fund revenues if the amendment was enacted. The opponents correctly pointed out that ". . . interest charges on the *BART* system alone. . . . could siphon off many millions of dollars annually."[12] If the highway program were to go on at its present (or moderately reduced) pace, substantial tax increases would be needed. If the program were to be reduced, it would result in a substantial diminution in highway construction activity and a loss in income and employment.

On balance, the initiative offered a rather complex package of tradeoffs to the voters. It would have given communities the option of substituting mass transit expenditures for outlays on highway construction and maintenance, a tradeoff among two collective services. Further, it would have allowed the state legislature to allocate previously earmarked highway funds to air pollution control research; hence another potential substitution among collective services. Implicit in the proposition was a third tradeoff between private and public expenditure. While Proposition 18 did not specifically provide for an increase in the state gasoline tax rate, the nature of the initiative made this outcome likely.[13]

As with the Coastal Initiative, voting results for the Rapid Transit Initiative were taken from the report of the California Secretary of State. In addition to data on per capita income, educational attainment, and political preference previously described, observations on percent transport workers W', population density D, and total land area A in various cities were taken from the 1970 U.S. Census report. Finally, a dummy variable B was included to indicate membership of a city in the *BART* District.

To the extent that the measure was expected to enhance air quality, both through a substitution from private autos to rapid transit and via increased state effort in air pollution control research, the income term will reflect citizen demands for air quality. On the other hand, the act intended to reduce highway congestion and travel times. The obvious relationship between income and the cost of time spent in transit means that the income term will reflect a combination of at least these two effects. It seemed likely that adoption of Proposition 18 would force a decline in highway construction and maintenance activity. The proportion of citizens employed as transport workers (corresponding to ΔI in (16)) was included to capture the potential adverse impact which such an outcome could have upon incomes and employment in the transport industry.[14] The special circumstances existing in the *BART* District indicated inclusion of the dummy variable B in the equation explaining yes votes. Since Proposition 18

---

[12] Secretary of State as cited in fn. 10, p. 4.

[13] Proposition 18 did not propose any specific outlays on either rapid transit or air pollution control research. Rather it granted state and local governments the opportunity to make such expenditures at the expense of outlays on highways if they so decided. Hence, in deciding how to vote, citizens had to weigh the merits of the measure from the viewpoint of a subjectively formed probability that the proposed options if granted would be exercised.

[14] Presumably, adoption of Proposition 18 would have damaged the competitive position of the highway transport sector of this industry vis-à-vis the other transport modes (rail, air, etc.). While it would therefore have been desirable to separate employment in highway transport from employment in other sectors, data were not available at this level of detail. Examination of a few large cities for which such data were available indicated that trucking services accounted for a much larger share of transport industry employment than any of the other sectors.

[a] Standard errors in parentheses.

offered these cities the opportunity to limit tax increases by transferring existing revenue from highway uses to finance existing debt, a positive coefficient is anticipated.

Since Proposition 18 proposed to allow municipalities to substitute against auto oriented public services toward the mass transit mode, the rate at which a municipality could potentially trade off or transform these services is relevant to the voting decision. Under the hypothesis that the mass transit alternative is potentially more efficient in large dense cities, the variables *A* and *D* were included. However, large dense cities are also areas where existing levels of air quality were lowest, so that the variables *A* and *D* may in part also reflect differential citizen demands for air pollution control.[15] Fortunately, both of these effects should work in the same direction so that positive coefficients are expected for these variables.

As with the Coastal Zone Initiative, educational attainment and political preference were included to reflect variations in citizen preferences. Further, it was assumed that initial price levels and expected changes in prices were uniform throughout the state so that any price effects would be subsumed in the constant term.

The linear equation used to estimate $l(Y)$ (see (16)) incorporated all of the independent variables defined above. As before, the analog of equation (17) utilized educational attainment *E*, political preference *F*, and per capita income *I* as regressors. Joint estimation of these equations yielded the numbers reported in Table 2. Estimates of the structural parameters α, β, and γ, displayed in the third and fourth columns, were obtained by linear transformation of the estimated regression coefficients.

The signs of the parameter estimates in Table 2 are all plausible. The positive coefficient on income suggests that the demand for air quality is income elastic, or that the measure was expected to reduce congestion and travel times, or both. Although the coefficient associated with W' (percent transport workers) is not highly significant, its negative sign lends support to the hypothesis that Proposition 18 was expected to have an adverse effect upon incomes in that sector. Further, the findings corroborate contention that member communities in the *BART* District stood to benefit from Proposition 18, since it would have allowed them the opportunity to service their debt without tax increases.

---

[15] Unfortunately, comparable data on air pollution levels were not available for most of the cities in the sample.

Population density and land area also possess anticipated signs (positive). These results are consistent with the hypotheses that (i) the potential efficiency with which highway services can be transformed into rapid transit services is higher in large dense cities, and/or (ii) the comparatively low levels of air quality in such areas gives rise *ceteris paribus* to relatively intense demands for pollution control.

Both socioeconomic variables E and F appear significant, although no a priori expectations regarding the signs of their coefficients were formed. To the extent that Proposition 18 was viewed as an environmental protection measure, the coefficient on educational attainment is consistent with results obtained from the analysis of the Coastal Zone Initiative. The significant disapproval in areas with conservative voting records may reflect a preference for private auto transport over the more public mass transit mode. Estimates obtained for δ (fourth column of Table 2) are generally consistent in sign with those reported for Proposition 20 and are given a similar interpretation. The only anomalous result, the coefficient on income, has no obvious explanation.

To examine the significance of various groups of coefficients, the hypothesis testing procedure utilized in analysis of the Coastal Initiative was employed. The null hypothesis that the entire set of regressors in both equations was not significantly different from zero was rejected at 1 percent ($F(13,658)=130.3$). The hypothesis that the two variables density and land area were not significant was also rejected at 1 percent ($F(2,658)=8.5$). Finally null hypotheses were formed to examine the significance of the preference variables E and F in the two equations. The null hypotheses that these variables were not significantly different from zero in either equation yielded F-statistics of $(2,658)=45.3$ and $F(2,658)=73.8$, respectively, and were therefore both rejected at 1 percent.

IV. Conclusions

The purpose of this study was to develop a model of individual behavior that allows one to draw inferences about preferences from voting data. The results, although pertaining to only two issues, demonstrate the feasibility of this approach. Further, the results obtained cast doubt upon the notion that individuals somehow alter their preferences (or behavior) away from selfishness and toward the social good as they leave the market and enter the polling booth. To the extent that the impact of the proposed policy changes could be specified beforehand, observed voting responses were consistent with self-interest.

The two measures, although different in most respects, both dealt with improving environmental quality. One would therefore anticipate a degree of consistency between issues from variables that reflect attitudes and underlying preferences. Education, political preference, and income were chosen to represent voter predisposition. Tables 1 and 2 show a high degree of consistency in signs of preference variable coefficients obtained for the two issues. Not only are the results consistent between issues, they also support the growing evidence that environmental protection seems to be most favored by the affluent and well-educated segments of society.

Technical Change and the Reproducibility of Capital

By CHARLES R. HULTEN*

The conventional approach to the measurement of total factor productivity distinguishes between shifts in an aggregate production function (technical change) and movements along the production function (factor accumulation).[1] The former is conventionally measured as the residual growth rate of output not accounted for by the growth rates of factor input, and the importance of technical change as a source of economic growth is assessed by comparing this residual with the growth rate of real product.[2]

The conventional approach does not allow for the dynamic interaction of technical progress and capital accumulation. Capital is an output of the production process as well as an input, so that an increase in technical efficiency which leads to an increase in output will in general also lead to an increase in capital stock. This in turn results in a further increase in output, part of which is allocated to capital accumulation, and so on. Thus, when technology is changing, part of the observed capital accumulation must be recognized as having been induced by the changing technology. In assessing the importance of technical change as a source of growth, the effects of induced capital accumulation must be allowed for; the conventional "residual" does not take induced capital accumulation into account, and thus tends to misstate the importance of technical change as a source of growth.

L. M. Read and T. K. Rymes (1968, 1971) have attempted to account for the reproducibility of capital in purely technical terms by measuring capital in terms of the units with which it is produced. J. R. Hicks has proposed to account for reproducibility by measuring capital in terms of consumption foregone. A different approach is taken in this paper: reproducibility is allowed for by introducing intertemporal consumption decisions into the conventional total factor productivity model. Capital accumulation is determined endogenously in this framework, and this permits the analysis of the impact of technical progress on the rate of capital accumulation. It is thus the correct framework for assessing the importance of technical progress in the growth process, while the conventional residual is the correct framework for measuring the change in productive efficiency.[3]

---

* Assistant professor, The Johns Hopkins University. I would like to thank Carl Christ, Dale Jorgenson, Louis Maccini, and Jürg Niehans for their many helpful comments on previous drafts; remaining errors are, of course, my own.

[1] The literature on total factor productivity includes Laurits Christensen and Dale Jorgenson (1969, 1970), Edward Denison (1962, 1967, 1969, 1972), Jorgenson and Zvi Griliches (1967, 1972a,b), John W. Kendrick (1961, 1970), and Robert Solow. Critics of the total factor productivity approach include Luigi Pasinetti, J. R. Hicks, L. M. Read, and T. K. Rymes (1968, 1971).

[2] Actual estimates of the importance of technical change vary. For example, Solow finds that most (seven-eighths) of the growth in *U.S.* real product can be attributed to technical progress (for the period 1909–49). Jorgenson and Griliches (1967), on the other hand, find that nearly all the growth in real product can be attributed to factor accumulation (over the period 1945–65). More recently, Christensen and Jorgenson (1969, 1970) assign a relative importance of approximately one-third the growth rate of real product to technical change (for the period 1929–67).

[3] It is therefore incorrect to conclude, as does Rymes, that "the numbers generated by Denison, Kendrick,

In Section I, the effects of reproducibility are more fully analyzed, as is the relationship between the conventional approach and the approach of this paper. In Section II, a one-sector model of optimal growth is used to investigate the long-run equilibrium expansion of output in response to a changing technology. A rate of technical change (termed the "long-run Fisherian" rate) is defined which measures the total change in output as the economy fully adjusts in the long-run equilibrium to each new level of technology. This corresponds to measuring the shift in the technology along the long-run equilibrium path, as opposed to measuring the shift holding the capital-labor ratio constant, or the capital-output ratio constant, or the labor-output ratio constant. This new definition is the appropriate one for the sources of growth problem, since it measures the shifting technology along the growth path. The new definition is then related to the conventional Hicksian and Harrodian definitions of the rate and bias of technical change. In Section III, the assumption of long-run equilibrium is dropped, and a two-sector model of short-run equilibrium growth is analyzed. The motivation for this change of focus is empirical: the economy cannot be assumed to be on the long-run equilibrium path, if such a path even exists. A short-run index of technical change (termed the "short-run Fisherian" rate) is defined which allows for induced accumulation, and in Section IV this index is estimated using data from the Christensen-Jorgenson (1969, 1970) studies. The result is an estimate of technical change which is nearly twice the Christensen-Jorgenson estimate. While the assumptions underlying the estimation are indisputably crude, the result is at least suggestive of the possible margin by which conventional estimates misstate the contribution of technical change to economic growth.

I. The Reproducibility Problem

To focus more clearly on the issues involved, consider a one-sector economy in which the labor force is constant, and the rate of investment is just sufficient to meet replacement requirements on the existing stock of capital; with constant preferences and technology, the rate of output is stationary. Consider, now, the effect of a once-and-for-all Hicks-neutral shift in technology. The increase in productive efficiency will result in an increase in the rate of output, and the extra output will in general go to increase both consumption and investment. Total investment now exceeds replacement requirements, the capital stock increases, and the rate of output is again increased. The extra output is again divided between consumption and investment, and if the additional investment exceeds the extra replacement requirements generated by the initial increase in investment, the capital stock is further increased and the process is repeated. Each new increment of net investment generates a stream of replacement requirements, and the economy will come to rest (i.e., reach the new equilibrium) when the last increment to gross investment just equals the cumulative additional replacement. In the new equilibrium (b in Figure 1), the rate of output exceeds its previous level (a in Figure 1). The full effect of the change in technology is the amount of output above the initial equilibrium value.

The change in the Hicksian efficiency index from A_0 to A_1 thus results in a total

---

Salter, Solow, Griliches and Jorgenson are meaningless" (1971, p. 2). The total factor productivity framework does in fact retrieve the Hicksian efficiency parameter under the maintained hypothesis of competitive equilibrium and the existence of a Hicks-neutral aggregate production function. The issue confronted in this paper is whether these numbers accurately portray the true importance of technical change in the process of economic growth.

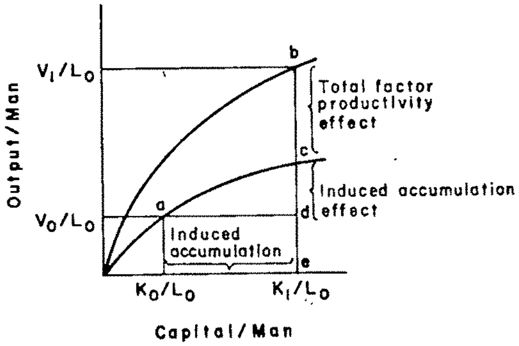

FIGURE 1

increase in output equal to the segment *bd*. The segment *bd* is itself composed of two effects: the change in output due to the increase in factor efficiency (the segment *bc*), and the change in output due to the extra capital induced by the increase in factor efficiency (the segment *cd*). The conventional total factor productivity index measures the ratio *be/ce*, and is thus a valid measure of the ratio of Hicksian efficiencies A_1/A_0. It is not a valid measure of the total importance of technical change, which is measured by the larger ratio *be/de*, because the expansion of capital per man induced by the change in technical efficiency is not allowed for. The magnitude of this induced accumulation effect depends on consumers' preferences for present versus future consumption. The greater the marginal propensity to save, the larger is the induced accumulation effect, and the greater is the margin by which the total factor productivity estimate understates the true contribution of technical change to total economic growth.

II. Long-Run Fisherian Technical Change

These conclusions can be generalized by considering a somewhat more formal model of optimal growth.[4] Consider a one-sector model where preferences for the economy as a whole can be represented by a utility function of the following form:

$$U = \sum_{t=0}^{\infty} a^t u(c_t) \tag{1}$$

where c_t represents per capita consumption, and a is a constant subjective discount factor, $0<a<1$. The function u is assumed to have the following properties

$$u' > 0, \quad u'' < 0 \qquad \text{for } c_t > 0$$

where u' and u'' are the first- and second-order derivatives of u, and to exclude corner solutions

$$\lim_{c_t \to 0} u'(c_t) = \infty$$

K_0 units of the commodity and L_0 units of labor services are initially available, and it is assumed that labor grows exogenously by a constant factor $n \geq 1$: $L_{t+1} = nL_t$. A constant returns technology is also assumed which relates the endowment available at the beginning of each period K_{t+1}, to that part of the previous period's endowment not consumed $K_t - C_t$, and to labor input L_t:

$$K_{t+1} = F(K_t - C_t, L_t) \tag{2}$$

Using lower case letters to denote per capita rates, we may write

$$k_{t+1} = f(k_t - c_t) = \frac{1}{n} F(k_t - c_t, 1) \tag{3}$$

The function f is assumed to have the usual neoclassical properties

$$f' \geqq \frac{1}{n} \qquad f'' < 0 \tag{4}$$

$$f(0) = 0 \qquad f'(0) = \infty \qquad f'(\infty) = \frac{1}{n}$$

where f' and f'' denote the first- and second-order derivatives of f.

The optimal consumption program is the solution to the problem

---

[4] This section follows the exposition of Nissan Liviatan rather closely.

$$\max U = \sum_{t=0}^{\infty} a^t u(c_t)$$

with respect to $c_0, c_1, \ldots$, subject to

$$k_{t+1} = f(k_t - c_t), \qquad 0 \le c_t \le k_t, \qquad t = 0, 1, \ldots, \text{ given } k_0$$

A necessary condition for an optimum is that the marginal rates of substitution in production and consumption must be equal for every t:

$$\text{(5)} \qquad \frac{u'(c_t)}{au'(c_{t+1})} = f'(k_t - c_t) \quad t = 0, 1, \ldots$$

Given assumptions about the discount factor and the concavity of the utility and production functions, condition (5) is also sufficient, provided $a^t u'(c_t) \to 0$ as $t \to \infty$.[5]

The assumptions also insure that the economy can achieve a unique stationary optimum. From (3) and (5), it follows that the stationary value $\bar{k}$ and $\bar{c}$ must satisfy

$$\text{(6)} \qquad \frac{1}{a} = f'(\bar{k} - \bar{c})$$

$$\text{(7)} \qquad \bar{k} = f(\bar{k} - \bar{c})$$

Conditions (6) and (7) completely characterize the stationary optimum. Recalling the example of the preceding section, the equilibria a and b of Figure 1 correspond to solutions of (6) and (7) for two technologies satisfying (4), and for the special case $n = 1$.

We have thus far not allowed for the possibility of technical change. As we are interested in the response of output to changes in technical efficiency, the specification of technology (2) is replaced with one which allows for shifts over time:

$$\text{(2')} \qquad K_{t+1} = F^i(K_t - C_t, L_t) \qquad i = 0, 1, 2, \ldots$$

We assume that each technology F^i, $i = 0, 1, 2, \ldots$, satisfies the conditions (4). Then, for each F^i there is a stationary optimum

$$[\bar{k}_i, \bar{c}_i] \qquad i = 0, 1, 2, \ldots$$

which are the solutions of (6) for each level of technology. The shift in technology from F^i to F^{i+1} has the effect of changing long-run equilibrium output from $\bar{k}_i$ to $\bar{k}_{i+1}$. Given the nature of the utility function (1), this change in output is solely the result of the changing technology, and is therefore equivalent to the Fisherian concept of technical change advanced in this paper. In terms of Figure 1, the ratio $\bar{k}_1/\bar{k}_0$ corresponds to the ratio be/de.

In the case where this technology shifts with sufficient smoothness over time, we can define the path of long-run optimal output $\bar{k}(t)$, which results for the changing technology.[6] A movement along this path indicates technical change in the Fisherian sense of this paper, and may be contrasted with the Hicksian definition of technical change, which is the change in output measured along a constant capital-labor path, and the Harrodian definition, which is the change in output measure along a constant capital-output path.

The rate of change of output along $\bar{k}(t)$ defines the long-run Fisherian *rate* of technical change. The problem is then to characterize this rate, $D\bar{k}(t)/\bar{k}(t)$, in terms of the total factor productivity effect and the induced accumulation effect. This can be done in a straightforward way by including time t as an explicit argument of the technology, and differentiating the second equation of (6) totally with respect to time (see fn. 6). This yields

$$\text{(8)} \qquad \frac{D\bar{k}}{\bar{k}} = \pi \frac{D\bar{\imath}}{\bar{\imath}} + T$$

where $\bar{\imath} = \bar{k} - \bar{c}$, π is capital's share of income, and T is the Hicksian rate of technical change[7] (the operator D denotes derivatives with respect to time, and time subscripts are suppressed for clarity). The left-hand side of (8) is the long-run Fisherian rate of technical change. The second term of the right-hand side T is the conventional total factor productivity effect, and the first term is the effect of induced accumulation.

---

[5] See Liviatan, pages 304–05, for further discussion.

[6] That is, we assume a continuous version of the model in which the technology is characterized by $K(t) = F(I(t), L(t), t)$, where $I(t) = K(t) - C(t)$. The restrictions (4) are assumed to hold for each t, and the optimal path $\bar{k}(t)$ is assumed to be once differentiable.

The marginal product of i (the first equation of (6)) is constant, which implies[8]

$$\frac{Di}{i} = \frac{\sigma}{1-\pi} T + \sigma R \tag{9}$$

where R is the Hicksian bias, and σ is the elasticity of substitution of capital for labor.[9] Substituting (9) into (8), and letting Z denote the long-run Fisherian rate of technical change, we have

$$Z = \left[1 + \frac{\pi}{1-\pi}\sigma\right] T + \sigma\pi R \tag{10}$$

It is immediately evident that in general, $Z \neq T$, implying a divergence between the actual changes in output resulting from a shifting technology Z, and the rate at which the technology is shifting in the sense of Hicks T.

The special case of Hicks-neutral technical change is of particular importance for the conventional analysis of productivity change. The total factor productivity indexes are Divisia line integrals[10] and therefore depend in general on the path of integration. Under Hicks neutrality, however, the line integrals are path independent, and this is consequently the case usually assumed. The implication of Hicks neutrality for the present analysis is that $Z > T$, since $R = 0$ by hypothesis (and $\pi > 0$ and $\sigma > 0$ in the underlying technology). In other words, when the total factor productivity index is independent of the path of integration, it understates the actual change in long-run optimal output, and hence the true contribution of technical change to economic growth.

The long-run Fisherian rate may also be expressed in terms of the Harrodian parameters of technical change. The Harrodian rate H and bias B may be defined in terms of the corresponding Hicksian parameters:[11]

$$\begin{aligned} H &= \frac{T}{1-\pi} \\ B &= [R(1-\pi) + T]\sigma - T \end{aligned} \tag{11}$$

Substitution of H and B for T and R from (11) into (10) yields

$$Z = H + \frac{\pi}{1-\pi} B \tag{12}$$

Therefore, under Harrod-neutral technical change ($B = 0$) the long-run Fisherian rate is equivalent to the Harrodian rate and equals the rate of change of output along the long-run balanced growth path.[12]

---

[7] The share of capital and the Hicksian rate of technical change are defined, respectively, as

$$\pi = \frac{F_K K}{F}, \qquad T = \frac{F_t}{F}$$

where F_K is the partial derivative of F with respect to K, and F_t the partial derivative with respect to t (in the technology of fn. 6).

[8] See Peter Diamond, p. 162, equations (7) and (8), for a description of the dynamic behavior of the marginal products of capital and labor in a one-sector model.

[9] The Hicksian bias and elasticity of substitution are defined, respectively, as

$$R = \frac{F_{Kt}}{F_K} - \frac{F_{Lt}}{F_L}, \qquad \sigma = \frac{F_K F_L}{F F_{KL}}$$

where F_L is the partial derivative of F with respect to L, and F_{Kt}, F_{Lt}, and F_{KL} denote the respective second-order partial derivatives of F with respect to K, L, and t.

[10] For a discussion of Divisia line integrals, see Marcel Richter.

[11] See John Fei and Gustav Ranis.

[12] An alternative approach is to define technical change with respect to the consumption path $\bar{c}$(t), rather than with respect to $\bar{k}$(t), as in this section. With suitable manipulation of (8) and (9), this alternative consumption rate can be characterized in terms of the Hicksian T and R or the Harrodian H and B.

III. Short-Run Fisherian Technical Change

From an empirical standpoint, it is somewhat implausible to assume that the economy moves along the long-run growth path, even if such a path actually exists. In this section, the somewhat weaker assumption is made that the economy is able to achieve a short-run competitive equilibrium at each point in time. In this context, a short-run Fisherian rate of technical change is defined which is the difference between the actual growth rate of real product DV/V and the growth rate of real product which would have occurred if technology had remained constant at the level prevailing in a given base year, DV^*/V^*:

$$(13) \qquad Z' \equiv \frac{DV}{V} - \frac{DV^*}{V^*}$$

Z' measures the growth rate of real product attributable purely to technical change, since DV/V measures the actual growth rate of real product while DV^*/V^* measures the growth rate attributable to the changing factor endowments, excluding the capital accumulation induced by the shifting technology (for this reason Z' is in general different from the Hicksian T). The term Z' is related to the long-run Z in the following way: if technical progress stops after some point in time t″, and if a long-run growth path exists and the economy is on this path at time t′, then the level index associated with Z' (i.e., the integral of the growth rate Z' over the interval [t′, t; t>t″]) converges to the level index associated with Z (the integral of Z over the interval [t′, t; t>t″]). In other words, the short-run and long-run indices of technical change converge.

For purposes of estimation, a two-sector model will be used. This avoids the necessity, implicit in the one-sector case, of imposing a unitary marginal rate of substitution between consumption and investment goods. Separate short-run Fisherian rates are defined for each sector:

$$(14) \quad Z_1' \equiv \frac{DC}{C} - \frac{DC^*}{C^*}, \quad Z_2' \equiv \frac{DI}{I} - \frac{DI^*}{I^*}$$

where C and I are consumption and investment, respectively, and asterisks (here and throughout) denote the values obtaining under a constant base year technology. The aggregate short-run rate of technical change is defined in (24) below, as the weighted sum of Z_1' and Z_2'. Each sector is assumed to possess a constant returns technology,

$$(15) \quad C = G(K_1, L_1, t), \quad I = H(K_2, L_2, t)$$

where $K = K_1 + K_2$ and $L = L_1 + L_2$ denote capital and labor, and t is introduced to allow for shifts in the technologies. Assuming that the economy maintains short-run equilibrium, total differentiation of (15) yields

$$(16) \quad \begin{aligned} \frac{DC}{C} &= \pi_1 \frac{Dk_1}{k_1} + \frac{DL_1}{L_1} + T_1 \\ \frac{DI}{I} &= \pi_2 \frac{Dk_2}{k_2} + \frac{DL_2}{L_2} + T_2 \end{aligned}$$

where $k_1 = K_1/L_1$ and $k_2 = K_2/L_2$, and where π_i and T_i are, respectively, the income share of capital and the Hicksian rate of technical change in the ith sector. Equations (16) constitute the basic model of the total factor productivity approach. All variables in (16) are observable, directly or indirectly, except T_1 and T_2, which are determined residually. The hypothetical C^* and I^* are determined by a similar set of equations, but without technical change

$$(17) \quad \begin{aligned} \frac{DC^*}{C^*} &= \pi_1^* \frac{Dk_1^*}{k_1^*} + \frac{DL_1^*}{L_1^*} \\ \frac{DI^*}{I^*} &= \pi_2^* \frac{Dk_2^*}{k_2^*} + \frac{DL_2^*}{L_2^*} \end{aligned}$$

The problem is to estimate C^* and I^*

given the path of total labor input DL/L, and the initial level of the capital stock $K^0=K_1^0+K_2^0$. We observe first of all that

$$(18)\qquad \frac{DL}{L}=\rho\frac{DL_1^*}{L_1^*}+(1-\rho)\frac{DL_2^*}{L_2^*}$$
$$\frac{DK^*}{K^*}=\theta\frac{DK_1^*}{K_1^*}+(1-\theta)\frac{DK_2^*}{K_2^*}$$

where $\rho=L_1^*/L$ and $\theta=K_1^*/K^*$. Also, assuming that replacement is a constant proportion δ of the capital stock, the basic accumulation equation is

$$(19)\qquad DK^*=I^*-\delta K^*$$

Preservation of equilibrium in the factor markets (i.e., equality of marginal products and factor price ratios) requires, in the absence of technical change, that

$$(20)\qquad \frac{1}{\sigma_1^*}\frac{Dk_1^*}{k_1^*}=\frac{1}{\sigma_2^*}\frac{Dk_2^*}{k_2^*}$$

where σ_i^* is the elasticity of substitution of capital for labor. Finally, the gross savings rate s^* is defined

$$(21)\qquad s^*=\frac{p^*I^*}{C^*+p^*I^*}$$

where p^* is the price of the investment good in terms of consumption. It can be shown that (see Peter Diamond, pp. 162–63):

$$(22)\qquad \frac{Ds^*}{s^*}=(1-s^*)\left[\frac{\pi_1^*(1-\sigma_1^*)-\pi_2^*(1-\sigma_2^*)}{\sigma_2^*}\cdot\frac{Dk_2^*}{L_2^*}+\frac{DL_2^*}{L_2^*}-\frac{DL_1^*}{L_1^*}\right]$$

in the absence of technical change.

If suitable restrictions are imposed on the technology and the gross savings rate s, estimates of the factor growth rates in each sector may be derived from (18)–(22). These estimates can then be used in (17) to calculate the growth rates of C^* and I^*. The simplest assumptions with which to work are

$$(23)\qquad s=\text{constant},\qquad \sigma_1=\sigma_2=1$$

This, of course, implies that the factor shares π_i are constant. Although these assumptions are arbitrary, they are not without empirical appeal. Alternatively, a more flexible technological specification, such as the *CES*, could be used, in which case

$$\frac{D\pi_i^*}{\pi_i^*}=(1-\pi_i^*)\left(1-\frac{1}{\sigma_i^*}\right)\frac{Dk_i^*}{k_i^*}\qquad i=1,2$$

For purposes of estimation, the assumptions (23) will be employed. It then follows immediately that

$$\frac{DL}{L}=\frac{DL_1^*}{L_1^*}=\frac{DL_2^*}{L_2^*},\quad \frac{DK^*}{K^*}=\frac{DK_1^*}{K_1^*}=\frac{DK_2^*}{K_2^*}$$

The growth rate of labor DL/L is given, and DK^*/K^* can be computed recursively from (19), given the initial value of K. Thus with constant factor shares,

$$\frac{DC^*}{C^*}=\pi_1\frac{Dk^*}{k^*}+\frac{DL}{L}$$

Given these estimates, the calculation of Z_1' and Z_2' is straightforward. An overall rate of technical change may be obtained by weighting the sector rates by the actual sector shares in total product:

$$(24)\qquad Z'=(1-s)Z_1'+sZ_2'$$

Finally, the conventional indexes of technology T_1 and T_2 can be subtracted from Z_1' and Z_2' to estimate the effects of induced capital accumulation.

Thus the conventional dichotomy between technical change and capital accumulation results in the following aggregate relationship:

$$(25)\qquad \frac{DV}{V}=\pi\frac{Dk}{k}+\frac{DL}{L}+T$$

where V is total real product, π the share of capital in total product, and $T=(1-s)T_1+sT_2$. The short-run Fisherian approach, on the other hand, results in a reallocation of the sources of growth:

$$\frac{DV}{V}=\pi\frac{Dk^*}{k^*}+\frac{DL}{L}+Z' \tag{26}$$

which takes into account the effect of the induced accumulation of capital (assuming, as before, constant shares).

IV. Empirical Application

The model was estimated using the Christensen and Jorgenson (1969, 1970) data for the private domestic economy. The results are presented in Tables 1 and 2. For the period 1948–66, short-run Fisherian technical change was found to have occurred at an average annual rate of 2.67 percent. This is nearly twice the 1.42 percent average annual growth rate of total factor productivity T, implying an induced accumulation effect of 1.25 percent per year. The average annual sector rates Z_1' and Z_2' were found to be 2.25 and 3.22 percent, respectively. Results for 1950–63 are similar. Unfortunately, estimates of the corresponding total factor productivities T_1 and T_2 are not available.

The importance of technical change as a source of economic growth is correspondingly higher in the new view. The Fisherian rate accounts for approximately 64 percent of the growth rate of real product. This compares with 34 percent for the total factor productivity rate. The increased importance assigned to technical change is, of course, due to the treatment of capital input as a source of growth. Over the period 1948–66, capital actually grew at an average annual rate of 4.22 percent. The projected rate of capital accumulation in the absence of technical change is estimated to have been only 1.49 percent per year.[13] Consequently, 2.73 percentage points of the actual growth rate of capital is attributed to induced accumulation, and assigned to technical change.

It is thus evident that the induced accumulation effect is a potentially important source of economic growth. Under the present assumptions, the effect attributable to induced accumulation is nearly equal in magnitude to the conventional total productivity effect. This conclusion does obviously depend on the validity of the assumptions: the constancy of the sav-

TABLE 1—AVERAGE ANNUAL PERCENTAGE GROWTH RATES O- PRODUCTIVITY

Variable	1948–66	1950–66
Total Factor Productivity T	1.42	1.33
Fisherian Factor Productivity, Z'	2.67	2.51
Fisherian Factor Productivity (C), Z_1'	2.25	2.17
Fisherian Factor Productivity (I), Z_2'	3.22	2.93

TABLE 2—SOURCES OF GROWTH OF REAL PRODUCT, 1948–66

(Average Annual Percentage Growth Rates)

	Christensen-Jorgenson	Fisherian
Real Product	4.15	4.15
Real Factor Input	2.73	1.48[a]
Capital	4.22	1.49
Labor	1.50	1.50
Technical Change	1.42	2.67
Relative Proportion of Technical Change	0.34	0.64

[a] The growth rate of real factor input should be a weighted average of the growth rates of capital and labor. The fact that the rate for real factor input is slightly below the input rates is due presumably to round-off error.

---

[13] The capital stock projections assume an average rate of replacement δ equal to 0.083. This is a weighted average of the Christensen and Jorgenson (1969, 1970) rates of replacement for plant and equipment. The value of π_1 was estimated from the share of capital in aggregate income π and the gross savings rate s, and found to be approximately 0.31. Alternative estimates of capital stock were projected using values for π_1 of 0.38 and 0.45, but the resulting differences were negligible.

ings rate and unitary elasticities of substitution. However, these assumptions are certainly not implausible, or at least not so implausible as to completely vitiate the empirical analysis. This would imply that a reassessment of the role of technical change in the growth process is in order.

Different rates of total factor productivity are found in other investigations. For the period 1950–62, Edward Denison (1969) obtains an average annual rate of 1.37 percent, Jorgenson and Griliches (1967) a rate of 0.30 percent, and Kendrick (1970) a rate of 2.01 percent, for the private domestic economy. For the same period, Christensen and Jorgenson find a rate of 1.33 percent per year, and the current estimate, gross of induced accumulation, is 2.51 percent per year. However, this latter estimate is not directly comparable to the alternate estimates of total factor productivity, since it is specific to the Christensen-Jorgenson data base, and would have to be altered in order to reflect the methodologies of the other studies. There is no reason to believe that the broad conclusions of this paper would be changed if this were done.

V. Conclusion

The problem of measuring disembodied technical change includes both the measurement of total factor productivity and the measurement of the importance of technical change as a source of economic growth. Existing studies have successfully dealt with the first aspect of the problem, but not the second. The importance of technical change depends not only on the change in total factor productivity, but also on the response of capital (and perhaps labor also)[14] to the change. When these induced effects are allowed for, technical change is seen to be potentially far more important than heretofore thought. While the estimates of this paper are based on somewhat arbitrary assumptions, they are at least suggestive of the possible magnitude by which the conventional total factor productivity approach understates the importance of technical progress.

Cross-Subsidization: Pricing in Public Enterprises

By GERALD R. FAULHABER*

The problem of pricing commodities produced in the presence of common costs by a publicly owned or regulated enterprise continues to be of great practical interest to regulators and policy makers. It has generated a rich literature in the fields of public finance and public utility regulation, dating back to the 1880's. The economics literature has by and large focused on the efficiency of such commodity prices, whereas public policy makers are also concerned about more loosely defined questions of equity: does a proposed price structure for the multicommodity enterprise "unduly" favor the consumers of one commodity at the expense of the purchasers of another commodity, i.e., does the price structure result in cross-subsidy?

A paradigm best serves to illustrate the problem: a profit-regulated railroad which interconnects two large cities also provides rail service to a smaller town located on the route between the two cities. The fares charged for passage from the small town are sufficient to generate revenues in excess of the additional costs of serving it, such as ticketing and station costs, but not sufficient to cover an equal or proportionate (however defined) share of the common costs, such as trackage, signaling, and trainyard costs. Since the small town is not paying its "fair share" of common costs, is it not being subsidized by the larger cities? Do not the railroad tariffs favor the town at the expense of the cities?

Provided the revenues realized from providing rail service to the town exceed the added costs, the answer must be in the negative. In fact, the provision of service under these circumstances (assuming the road's profits remain constant) may actually lead to lower fares for the two cities compared to the alternative of no service for the town at all. The principle was stated by E. Porter Alexander: "If the [New York to San Francisco] price is more than the additional outlay in doing it, as against leaving it alone, it is profitable to the railroad, and the business is moreover advantageous to the whole inland community served by the railroad. For . . . the more prosperous the road, the lower the local rates may be made" (p. 4). The argument is no less cogent today, as William Baumol and David Bradford point out: "For (particularly if the firm is subject to a constraint on its overall profit) the opening of a market which makes any net contribution [to common costs] may permit or may even require a reduction in prices elsewhere" (p. 278).

As a first approximation, we may use this intuitively appealing notion as the basis for a definition: If the provision of any commodity (or group of commodities) by a multicommodity enterprise subject to a profit constraint leads to prices for the other commodities no higher than they would pay by themselves, then the price structure is *subsidy-free*. Thus, a subsidy-free price structure insures that the provision of each commodity by the enterprise is "Pareto superior" to nonprovision.[1] Note, however, that a subsidy-free price structure is not necessarily welfare maximizing; nor are we entitled to assume that such price structures are morally superior to their subsidy-prone fellows on grounds of social justice. Subsidy-free prices do no more than insure that the production and sale of each commodity makes all consumers at least as well off as they would otherwise be.

---

* Bell Telephone Laboratories, Inc. I wish to express my thanks for the helpful comments and suggestions of William Baumol, David Bradford, and Michael Rothschild of Princeton University. I am also indebted to my colleagues at Bell Laboratories, especially Elizabeth Bailey and V. S. Bawa for their very useful criticisms. This work was inspired by the earlier research of Edward Zajac, to whom I am especially indebted for continuing discussions on this work. Of course, responsibility for errors is mine.

We shall see, however, that our subsequent extension of the definition of subsidy-free prices as the solution set to an n-person cooperative game leads to rather strong conclusions concerning the stability of a competitive market, the cogency of the "natural monopoly" argument, and the choice between protected monopoly and open competition.

I. The Enterprise as a Cooperative Game

We restrict our attention to enterprises which (a) produce and sell at least two differentiable products which can be priced separately, and (b) operate under a constraint on total profit requiring total revenues to exceed the sum of the added costs of each commodity. The natural candidates to fulfill conditions similar to (b) are enterprises characterized by economies of joint production[2] subject to a break-even constraint, such as privately owned publicly regulated utilities, or a publicly owned enterprise required to "stand on its own bottom" (to use Harold Hotelling's mixed metaphor), such as a bridge or turnpike authority.[3] Without loss of generality, we may assume that total profits (earnings in excess of the cost of capital) are constrained to be zero.[4,5]

As an example, suppose we consider the supply of water to a residential community, when commodity i is water delivered to neighborhood i (or perhaps household i).[6] We denote the set of neighborhoods (commodities, consumer groups) by $N=\{1, 2, \ldots, n\}$, where $q_1, \ldots, q_n$ are the amounts of water supplied to each neighborhood. We adopt the notation that for all subsets $S\subseteq N$, q^S is an n-vector for which

$$q_i^S = \begin{cases} q_i & i \in S \\ 0 & i \in N - S \end{cases}$$

so that $q^N=(q_1, q_2, \ldots, q_n)$ and $q^{\{1\}}=(q_1, 0, \ldots, 0)$.

There are many production arrangements by which water can be supplied: each neighborhood can have its own well, storage tank, and pumps; groups of neighborhoods can have common facilities; or the entire community can use one common facility. The technology of water recovery, storage, and distribution we consider to be available to all, and representable by a cost function $C(\cdot)$ defined over n-vectors, i.e., the cost of supplying water to the set $S\subseteq N$ of neighborhoods is $C(q^S)$. Thus, if neighborhood 1 constructed its own well, pumps, and storage tank, the cost would be $C(q^{\{1\}})=C(q_1, 0, \ldots, 0)$, and the total cost if all neighborhoods were to supply themselves would be $\sum_{i=1}^{n} C(q^{\{i\}})$. At the other extreme, if a single enterprise served all neighborhoods, the total cost would be $C(q^N)$. Our assumption of economies of joint production is expressed in cost function terms by requiring that $C(\cdot)$ satisfy for all S, $T\subseteq N$, with $S\cap T=\phi$, and any $q_i\geqq 0$

---

[1] In the sense used by James Quirk and Rubin Saposnick (1968): each consumer finds the state in which each commodity is provided by the enterprise to be preferable to the state in which only some of the commodities are provided by the enterprise. This interpretation was pointed out to me by Baumol.

[2] One could imagine a government-owned firm with constant returns to scale, but where the firm is required to contribute a fixed sum annually to the state's coffers.

[3] The imposition of the profit constraint, of course, precludes strict marginal cost pricing. An extensive literature, beginning with Hotelling, suggests the desirability of marginal cost pricing with public subsidies to cover deficits in increasing return industries; the difficulties affecting this approach are well known, and concisely discussed by Nancy Ruggles. As has often been pointed out, it is not easy to devise a tax or subsidy which will not affect the marginal conditions. Clearly, our problem lies in the area of the second best.

[4] We assume throughout that the enterprise operates efficiently, and is regulated or managed to just earn its cost of capital. There is an extensive literature in public utility regulation which addresses the difficulties of achieving what we so blithely assume, treated most recently and most elegantly by Elizabeth Bailey. Such issues are not the focus of this paper.

[5] We may interpret positive profits as a subsidy of producers (investors) by consumers, and negative profits as a subsidy of consumers by producers. Thus, our zero-profit constraint may itself be viewed as a requirement of subsidy-free operation. As previously asserted, however, the analysis requires only that the profit constraint satisfy condition (b) above

[6] Although in our example the output commodities differ only in the location to which they are delivered, the analysis holds in more general circumstances; for example, a dam can supply three commodities: flood control, water for irrigation, and electric power.

$$C(q^S) + C(q^T) \geqq C(q^{S+T}) \tag{1}$$

That is, the cost of supplying water to two groups of neighborhoods jointly is less than separate supply, at any demand levels q_i.

On the demand side, we assume that quantities demanded are a function of own price only,[7] i.e., $q_i=q_i(p_i)$, where $p_i=$ price of the ith commodity. To maintain consistent notation, we denote the revenues from neighborhood i as $r_i=p_i\cdot q_i(p_i)$, and

$$R(q^S) = \sum_{i\in S} r_i = \sum_{i\in S} p_i\cdot q_i(p_i)$$

Once a particular supply arrangement has been determined, then the suppliers are held to a zero-profit constraint. For example, if the set $S\subseteq N$ is served by one supplier who supplies set S only, then the prices p_i, $i\in S$, must satisfy

$$R(q^S) - C(q^S) = \pi(q^S) = 0 \tag{2}$$

where the above equation (2) defines the profit function $\pi(\cdot)$.

In view of inequality (1), it is clear that the arrangement in which one producer supplies the entire community at the levels q^N is at least as efficient as any other arrangement, and that if the inequality is strict, the single supplier is the uniquely most efficient production arrangement.[8] From the point of view of the application of these concepts, we are interested in prices which will induce and preserve the "coalition of the whole," i.e., the single supplier arrangement. Thus, the relevant constraint is

$$R(q^N) - C(q^N) = \pi(q^N) = 0 \tag{2'}$$

The reader who is familiar with the theory of n-person cooperative games (see, for example, Robert Luce and Howard Raiffa) may recognize the structure of our "game"; for *given demand levels* $q_1, \ldots, q_n$, the neighborhoods (or consumer groups) are the "players," the function $C(\cdot)$ is the characteristic function, denoting the value of the game as played by all possible coalitions $S\subseteq N$ of players, and the vector of revenues $\{p_iq_i\}$ is the "payoff" vector.[9] Expression (1) is the condition of subadditivity, which insures that there are incentives to cooperate. The economic interpretation is that of a natural monopoly, a classic case for public control (see, for example, Alfred Kahn). Equation (2), our zero-profit constraint, corresponds to the game theoretic condition that all the "value" of the games be shared amongst the players via the payoff vector.

---

[7] The more interesting and more difficult case of interrelated demand functions is treated later in the paper. Also note that a single price prevails, levied on each unit consumed. We do not treat the case of a multipart tariff, e.g., a connection charge plus a consumption charge.

[8] The zero-profit assumption is most crucial here.

[9] In the standard game theory formulation, payoffs are received by the players, whereas in our game, revenues are paid out by the players. The correspondence may be made formally complete by changing signs (e.g., payoffs are negative revenues) and thus reversing the direction of all inequalities.

For a given subadditive characteristic (cost) function $C(\cdot)$, when is a payoff vector $r_1, \ldots, r_n$ a "solution" to the game? Loosely speaking, a payoff vector is a solution if it induces all (rational) players to cooperate, thus achieving (by expression (1)) the highest valued (least cost) game. At the given demand levels, if each neighborhood i is to be induced to join, then prices p_i must satisfy

$$(3) \qquad R(q^S) \leqq C(q^S) \qquad \forall S \subseteq N$$

That is, in order to induce each neighborhood $i \in N$, and each group of neighborhoods $S \subseteq N$ to cooperate, the community water company's prices should be such as to make it more costly for any group of neighborhoods to "go it alone."[10] In the parlance of game theory, revenue vectors which satisfy (2′) and (3) constitute the core of the game, as defined by D. B. Gillies. We can now formalize our definition of subsidy-free prices: prices for which the resulting revenue vector lies in the core of the game are subsidy-free.

Another interpretation of subsidy-free prices may be obtained by subtracting (3) from (2′) to obtain

$$(3') \qquad R(q^S) \geqq C(q^N) - C(q^{N-S}) \qquad \forall S \subseteq N$$

That is, the revenues contributed by the set of neighborhoods $S \subseteq N$ should be at least as great as the added cost of supplying S, in order to be subsidy-free.

A simplified version of (3′) involving only single-element sets has been known in the public utility field for some time, and has been called the incremental cost test. Its lineage is ancient, dating back to Alexander, as we have seen, and was recently restated by Kahn. However, this test for cross-subsidy is generally used to examine a single product or service, rather than groups of products, which, as we shall see below, can be misleading.

We might also interpret (3) as a "stand-alone" test, and although it is logically equivalent to (3′) when used in conjunction with (2′), it has received almost no attention in the literature of regulation or public utility economics. Exceptions are Karl Borch in his game theoretic treatment of automobile insurance rates in which expressions (2′) and (3) play a role, and a reference by Harry Trebing to rate maxima determined by such a stand-alone criterion.[11]

An example will serve to illustrate these ideas, in particular the importance of examining all subsets $S \subseteq N$ rather than only individual consumer groups $i \in N$. Suppose our water company serves four neighborhoods, with neighborhoods 1 and 2 east of the well, and neighborhoods 3 and 4 west of the well. The cost of the well and storage tank is \$200; in addition, the firm has an eastbound trunk line and pumping station for q_1 and q_2, as well as similar facilities devoted to q_3 and q_4, each of which costs \$100. In addition, the distribution costs for delivery of $q_i = 10{,}000$ gallons/day to each neighborhood are \$100, comprised of \$80 for the local distribution mains, plus \$.002 pumping costs, or \$20. Thus, if all neighborhoods are served by the single water company, total costs are \$800, or

---

[10] Of course, if neighborhood i actually did go it alone, the supply arrangement would change and prices would have to change, since (3) would not satisfy the zero-profit constraint. In our example with fixed (inelastic) demands, if $r_i \leqq C(q^{\{i\}})$ and yet neighborhood i tried to go it alone, its price would rise from p_i to p_i', where

$$p_i' - p_i = \frac{C(q^{\{i\}}) - r_i}{q_i} \geqq 0$$

[11] Trebing states: "A more meaningful standard might relate maximum rates to the cost of a single purpose facility or system built to serve the user requirements of the particular group most affected by the upper price limit. If this group paid a rate in excess of the cost of the single purpose facility, it would be subsidizing other user groups as well as failing to participate in any of the economies of joint-cost inherent in public utility operation" (p. 69).

$$C(q_1, q_2, q_3, q_4) = \$800$$

If any one neighborhood i were to go it alone, the only costs incurred would be the well, tank, and distribution system, so that

$$C(q_1, 0, 0, 0) = C(0, q_2, 0, 0) = C(0, 0, q_3, 0) = C(0, 0, 0, q_4) = \$300$$

Any two adjacent neighborhoods, i.e., 1 and 2, or 3 and 4, need only construct the well, tank, and two distribution systems, so that

$$C(q_1, q_2, 0, 0) = C(0, 0, q_3, q_4) = \$400$$

Two (three) nonadjacent neighborhoods would find it necessary to build well, tank, two (three) distribution systems, and a trunk line and pumping station to the nonadjacent neighborhood, yielding

$$C(q_1, 0, q_3, 0) = C(q_1, 0, 0, q_4) = C(0, q_2, q_3, 0) = C(0, q_2, 0, q_4) = \$500$$

$$C(q_1, q_2, q_3, 0) = C(q_1, q_2, 0, q_4) = C(q_1, 0, q_3, q_4) = C(0, q_2, q_3, q_4) = \$600$$

What revenue vectors are subsidy-free? Using (2′), (3), and (3′), some manipulation will show that the relevant relations are

$$\begin{aligned} r_1 + r_2 + r_3 + r_4 &= \$700 \\ r_i &\geqq 100 \\ r_1 + r_2 &\geqq 300 \\ r_3 + r_4 &\geqq 300 \end{aligned}$$

Will the time-hallowed incremental cost test applied singly to each service ($r_i \geqq 100$) be sufficient to detect subsidy? Unfortunately, no; suppose the price per gallon to the eastern neighborhoods is 1.2¢, and to the western neighborhoods is 2.3¢. Then $r_1 = r_2 = \$120$, and $r_3 = r_4 = \$230$. Clearly, total revenues just equal total costs, and each neighborhood is paying more than its incremental cost of \$100. However, it is clear that neighborhoods 1 and 2 together, the eastern neighborhoods, are not paying in total their joint incremental cost of \$300, which includes not only the two distribution systems, but the eastbound trunk line and pumping station costs of \$100. Their combined revenue of \$240 falls short of their combined incremental cost, i.e., $r_1 + r_2 < 300$. The problem arises because the trunk line and pumping costs are joint among a subset of neighborhoods, larger than a single neighborhood and smaller than the entire collection of neighborhoods.[12] If all costs were either directly attributable to a single neighborhood (i.e., could be avoided were that neighborhood to drop out of the coalition) or were joint among all neighborhoods, then an incremental cost test for each service taken one at a time would suffice. The presence of costs which are joint among a proper subset of the whole coalition imply the necessity of testing that subset for cross-subsidy.[13]

---

[12] A similar calculation shows the same difficulties in applying the "stand-alone" test of (3). If each neighborhood tried to go it alone, they would individually incur well, tank, and distribution costs of \$300 each, which is greater than the revenues of any of the neighborhoods under price structure (9), thus satisfying (3). However, if the western neighborhoods decided to "go it alone, together," their total stand-alone costs would be \$400, which is less than their combined \$460 expenditure.

[13] The application of game theory to public enterprise pricing has been the subject of several recent articles. S. C. Littlechild, Edna Loehman and Andrew Whinston (1971, 1974a,b) recommend the use of the Shapley value of the appropriately defined game, on the basis of its purported "fairness" and "equity." In this paper, the emphasis is not on finding a unique set of prices which is "fair," but rather on determining a set of prices, all of which are subsidy-free, and, as we discuss below, provide the appropriate incentives for consumer groups to seek the most efficient means of supply in the presence of joint production. This leads us to the core as a solution concept; as the Shapley value need not lie in the core of the game, we find it of less interest than the cited authors. Our approach is much closer in spirit to the literature in club theory, such as James Buchanan and Mark Pauly (1967, 1970). Pauly considers core solutions as club equilibria, i.e., as a means of inducing and preserving optimal size clubs. In our case, core solutions have similar incentive properties, and the

Although prices are our major interest, the analysis so far has treated them as simply a way to obtain revenues r_i from fixed quantities q_i, where the revenues play the key role in the core constraints. Suppose that both (2′) and (3) were satisfied for some demand levels $q_1, \dots, q_n$, at prices $p_1, \dots, p_n$, but that some set $S \subseteq N$ of consumers thought they would obtain lower prices by going it alone. This would change the supply structure so that one enterprise supplied the rebellious consumers of S, while presumably another enterprise supplied $N-S$. The zero-profit constraint would apply to both so that in view of (3), prices and hence quantities need adjust accordingly to $\bar{p}_1, \dots, \bar{p}_n$ and $\bar{q}_1, \dots, \bar{q}_n$. At the new demand levels it may be the case that $\bar{p}_i \leqq p_i$ for $i \in S$, even though (3) holds at the old demand levels. Thus, consumers in S may be better off by going it alone even though $r_1, \dots, r_n$ is in the core.

We show that this cannot occur, provided that the function $\pi(q^S) = R(q^S) - C(q^S)$ has a positive derivative with respect to price p_i for all $i \in S$.[14] To prove this, we will show that uniformly lower prices for any set $S \subseteq N$ cannot satisfy the zero-profit constraint for that set S provided (3) is satisfied and the derivative of $\pi(q^S)$ with respect to p_i for all $i \in S$ is positive.

Suppose that at prices $p_1, \dots, p_n$, (2′) and (3) are satisfied for all $S \subseteq N$, and the derivatives of $\pi(\cdot)$ are positive, as assumed. For any set $S \subseteq N$, let $\bar{p}^S$ be a price vector for S such that for all $i \in S$ $\bar{p}_i \leqq p_i$, and for at least one $j \in S$, $\bar{p}_j < p_j$. Since (3) is satisfied at prices $p_1, \dots, p_n$ and quantities $q_1, \dots, q_n$ and all cross-elasticities are zero, then

$$
\begin{aligned}
0 \geqq \pi(q^S) &= \pi\{q(\bar{p}^S)\} + \sum_{i \in S} \int_{\bar{p}_i}^{p_i} \frac{\partial \pi}{\partial x_i}\, dx_i \\
&> \pi\{q(\bar{p}^S)\} = R(\bar{q}^S) - C(\bar{q}^S)
\end{aligned}
$$

Hence, for any $S \subseteq N$ and any set of prices $\bar{p}^S$ which would induce S to go it alone, the resulting coalition would be infeasible in that revenues would not cover costs for the rebellious coalition S.

Clearly, this result is quite helpful as a practical matter to policy makers concerned with determining whether or not a given rate structure is subsidy-free. When considering if any consumer group would be better off on a stand-alone basis, the regulator need not calculate a new set of prices and demands which would obtain under the hypothetical stand-alone arrangement, but need only calculate revenues based on the given price structure and demand levels, and the costs of the hypothetical arrangement based on the given demand levels (assuming, of course, the conditions of the theorem are fulfilled). One needs no information about demand elasticities but rather only information about the costs of alternative supply arrangements at the given demand levels to

---

optimal size "club" is the entire set of players, since the economies of joint production are assumed to prevail up to the entire set N. My work differs from Pauly's principally in that I am concerned with pricing rules for divisible commodities rather than entry fees to a club. Further, Pauly's major results are for the case of identical consumers, although he generalizes this in his 1970 paper, where the optimal club size is small relative to the size of the population as a whole. In the present paper, not only are consumers different on the demand side, but also on the supply side; the cost of serving different consumer groups may differ. In addition, I concentrate on the case where economies of joint production encompass the entire relevant population.

[14] We argue for the plausibility of this assumption as follows: suppose $\pi(q^s)$ as a function of p_i is concave and achieves a maximum at some positive level of profits. If the profit constraint is binding, then $\partial\pi(q^S)/\partial p_i \neq 0$. The firm's constrained maximum could occur at a lower price, where $\partial\pi(q^S)/\partial p_i > 0$, or at a higher price, where $\partial\pi(q^S)/\partial p_i < 0$ (by concavity of π), and a profit-maximizing firm would in theory be indifferent between the two points. However, at the lower price, output would be higher, sales (it turns out) would be higher, and consumers happier. Since all are at least as well off at the lower price, the firm would have to be perverse indeed to operate where $\partial\pi(q^S)/\partial p_i < 0$. Hence, we may safely assume, barring ignorance or malice, that $\partial\pi/\partial p_i > 0$.

determine whether or not prices are subsidy-free in the zero cross-elasticity case.

II. Market Incentives and Welfare Maximization: Some Implications

Before moving on to the technically more difficult discussion of cross-subsidization when demands for the commodities are interrelated, we explore first the issue of incentives to competitive entry and subsidy-free prices; second the relation of welfare maximizing prices to subsidy-free prices; and third the question of existence of subsidy-free prices.

Recall that our definition of subsidy-free prices as the core of the game focusses on the inducement aspect: a price structure which is subsidy-free is Pareto superior to what prices would otherwise be for each consumer group or coalition of consumer groups. Thus, all groups can in principle be induced to join the overall (and most efficient) coalition, since the benefits of increasing returns are distributed in some measure to each group. A public enterprise with economies of joint production extending to the entire market and whose prices lie in the core is the classic case of a natural monopoly;[15] the distribution of the economies of joint-cost operation are such that no firm would find it profitable to enter the market for some subset of the enterprise's consumers in view of (3). If there are economies of joint operation and prices are not in core, however, then at least one coalition will have strong incentives to find themselves an entrepreneur and split off from the enterprise, thus leading to a globally less efficient supply arrangement. If free entry into the market is the rule, then if the public enterprise chooses prices outside the core, market forces should be expected to lead to the virtual breakup of the enterprise!

As pointed out before, prices which are subsidy-free do not necessarily promote the common weal or bring about social justice. The regulators of our public enterprise may deliberately choose a policy of subsidization, and price the commodities of that enterprise accordingly. Our analysis indicates that such prices would produce market incentives for the erosion of the firm offering the economies of joint production by competitive entry. If the public authorities desire both subsidizing prices *and* economies of scale, then the coercive authority of the government must be employed to restrict or prohibit entry into the market. Thus, even when the public enterprise enjoys increasing returns to scale, if the regulators adopt a pricing policy of subsidization as we have defined, entry must be restricted.[16] On the

---

[15] Typically, natural monopoly is discussed in terms of an enterprise producing only one commodity with increasing returns to scale. This situation is simply a special case of (1), since with a single commodity, for any arbitrary partition of the consumers into n groups, we can define our cost function

$$C(q_1, \ldots, q_n) = C\left(\sum_{i=1}^{n} q_i\right) = C(q)$$

Condition (1) then states that it is less costly to have one enterprise produce the entire supply of the single commodity than to split the supply function among two or more producers, which is precisely the meaning of natural monopoly.

[16] At least two caveats must be added to this discussion of competitive entry, both relating to the limitations of this static analysis when applied to actual pricing decisions. First, it may be the case that the opportunities for alternative supply arrangements may change drastically once a decision has been reached on a particular cooperative arrangement. For example, prior to the construction of a dam, those who dwell in the river's flood plain have the option to provide flood control through a distributed network of upstream catch-pools. Once the dam is built, however, the lake which builds up behind the dam may preclude the catch-pool method of flood control. Consumer groups whose options for alternative supply are few *ex post* can perhaps be expected to seek long-term contracts or commitments *ex ante*, when they have more options for alternative supply, and hence a more favorable bargaining position.

The second problem arises when technological innovation changes the nature of the game. Dynamic changes of this nature may affect not only the level of costs, but also the cost structure of the industry, turn-other hand, if the price structure is subsidy-free, then no such protection is needed since competitive entry is not feasible in view of (3).

Suppose that a regulator deliberately adopts a policy of cross-subsidization in his pricing decisions. Would such regulation necessarily violate some principle of welfare maximization, thus leading to subsidization? Indeed not; as it shall be shown, there is no a priori reason to expect that prices which maximize welfare subject to a break-even constraint will necessarily be subsidy-free. Intuitively, we might expect this since differences among constrained welfare-maximizing prices depend on differences in demand elasticities as well as costs, whereas whether prices are subsidy-free or not depends on the costs of alternative supply arrangements.

To illustrate this point, let us return to our water company, where the managers/regulators are maximizing welfare subject to a profit constraint, à la Frank Ramsey, M. Boiteux, and Baumol-Bradford. Specifically, we assume our water company: (a) views the incomes of consumers and the prices of all other commodities as fixed; (b) is required to break even; (c) faces zero cross-elasticities of demand among the different neighborhoods; and (d) wishes to maximize welfare subject to (a), (b), and (c). It is well known that prices thus determined have their percentage deviations from marginal cost inversely proportional to the price elasticity of demand, which prices Baumol and Bradford call "quasi optimal." That is,

$$(4) \qquad \frac{p_i - MC_i}{p_i} = \frac{k}{\epsilon_i} \qquad i = 1, 2, \ldots, n$$

where ϵ_i is the elasticity of demand with respect to price for the ith consumer group, and MC_i is the marginal cost of commodity i.

Returning to our previous example of the community water company, the relevant marginal cost is the pumping cost per gallon of \$.002. Further, assume that the consumers of water in neighborhoods 3 and 4 are more insistent upon watering their lawns than the consumers in neighborhoods 1 and 2, so that[17] $\epsilon_1 = \epsilon_2$ and $\epsilon_3 = \epsilon_4$, but that $\epsilon_3/\epsilon_1 = \epsilon_4/\epsilon_2 = .91$, i.e., groups 3 and 4 have a less elastic demand than groups 1 and 2. With this not very great difference in elasticities, and a marginal cost of $.002 = MC_i$, we find that the quasi-optimal prices are $p_1 = p_2 = .012$, and $p_3 = p_4 = .023$, which prices we have already shown involve a subsidy.

Since quasi-optimal prices depend on marginal costs and demand elasticities, whereas the constraints defining subsidy-free prices depend on the costs of alternative means of supply, it is no surprise that the two ideas are not necessarily compatible. Baumol-Bradford implicitly assume away the possibility of competitive entry, an assumption that is quite in keeping with their optimal taxation approach. Competitive entry, however, is the key idea of core constraints, and therein lies the crucial difference between the two results: the Baumol-Bradford optimal taxation approach is to maximize welfare subject to a break-even constraint, without regard to possible competitive entry or alternative means of supply (and

---

ing a joint cost, increasing returns enterprise into a constant returns business (e.g., the advent of freight transport by truck in competition with established rail transport), or vice versa. Although its difficulty and importance to public policy are clear, the problem is not treated in this paper.

[17] It should be borne in mind that the demand function to which we refer reflects the utility maximizing behavior of the consumer group, and is *not* the demand function seen by the water company. This latter function would become more elastic than the true demand function of the consumer group in the region where price was sufficiently high to make alternative means of supply attractive to the consumer. Thus, our demand elasticity measures consumer's attitudes toward the commodity *only*, and *not* the cost of alternative supply, or the degree of competition in the market.

hence, cross-subsidy). The cross-subsidy approach focuses on the costs of alternative supply to determine a set of prices, all of which provide positive incentives to forestall inefficient entry, and does not address directly the welfare maximization question.

If our public enterprise satisfies condition (1) so that it offers economies of joint production, are we assured that the core is never empty? Surprisingly and unfortunately, the answer is no; it appears that in a situation where average costs at first decrease and then increase, we may fail to obtain a core. Let us consider a new water company, located in the county next to our old water company. Our new company has three neighborhoods clustered about it, so all it need do to supply any one or combination of the three is to drill a well, build a storage tank, and construct the appropriate number of local distribution networks, the last item costing \$100 apiece, including pumping costs for 10,000 gallons/day/neighborhood. A geologist determines that a shallow well can be drilled to yield a maximum of 20,000 gallons/day at a cost of \$200 (including tank). If a higher output is desired, a deeper well must be drilled, at a cost of \$350. Thus, for $q_i = 10{,}000$, $i = 1, 2, 3$,

$$C(q_1, 0, 0) = C(0, q_2, 0) = C(0, 0, q_3) = \$300$$
$$C(q_1, q_2, 0) = C(q_1, 0, q_3) = C(0, q_2, q_3) = \$400$$
$$C(q_1, q_2, q_3) = \$650$$

since only the coalition of all three with its total demand of 30,000 gallons/day needs the more expensive well. Clearly, (1) is satisfied, but no core exists, since the core constraints are

$$\begin{aligned} r_1 + r_2 &\leqq 400 \\ r_1 + r_3 &\leqq 400 \\ r_2 + r_3 &\leqq 400 \\ 2(r_1 + r_2 + r_3) &\leqq 1200, \\ \text{or} \quad r_1 + r_2 + r_3 &\leqq 600 \end{aligned}$$

which cannot hold, since $r_1 + r_2 + r_3 = \$650$.

The existence of joint cost enterprises for which there are no prices free of subsidy could present serious difficulties in view of our discussion of market incentives. If no core exists and if entry into the market is free, then there will be no stable supply arrangement, since for any set of prices for any production and supply arrangement, there will always be an incentive for an entrepreneur to offer a new coalition lower prices in a new supply arrangement. Not even the coalition of all consumer groups can block this unstable behavior. In order to insure the stability of the most efficient cooperative solution, coercive intervention to restrict market entry becomes necessary.

III. The Cooperative Game with Interrelated Demands

In Section I, we considered the case of a multicommodity enterprise in which the demand for commodity i depended only upon the price of commodity i. In modeling the enterprise as a cooperative game, we assumed that demand and supply levels remained fixed, even under alternative supply arrangements. We then showed that if prices were subsidy-free in the "fixed demand" game, they remained so when prices and quantities changed under various supply arrangements provided that the cross-elasticities of demand are zero.

Unfortunately, no such simplifying result holds in the presence of cross-elasticities. For consider a firm which is about to offer a new service or commodity for sale; the new service will add to both the revenues and the costs of the firm. Our previous analysis suggested that if the added revenues exceeded the added costs, then the service was not being subsidized and in fact was a benefit to the other services. We therefore compared the revenues collected from this service with its incremental costs. However, in the presence of cross-elasticities, the revenues collected from the new service do not measure the added, or incremental revenues, since revenues from the other services may rise (if the service in question is a net complement) or decline (if the new service is a net substitute). If we consider varying prices, then the core will be smaller or larger than the fixed demand core, depending on whether the service is a substitute or complement for the remaining services.

To see this, we first define our "varying demand" game in so-called generalized characteristic function form (see Scarf).[18] Let

$$\pi(q^S) = R(q^S) - C(q^S)$$

where $q_i = q_i(p_1, \ldots, p_n)$.

$$\begin{aligned} (5) \qquad V^N &= \{p^N \mid \pi(q^N(p^N)) = 0\} \\ V^S &= \{p^S \mid \pi(q^S(p^S, p^{N-S})) \geqq 0 \\ &\qquad \text{for all } p^{N-S} \text{ for which} \\ &\qquad\qquad \pi(q^{N-S}(p^S, p^{N-S})) \geqq 0\} \end{aligned}$$

Clearly, V^N is the set of prices satisfying the zero profit constraint; V^S, however, needs explaining. In words, V^S is the set of prices for the coalition S which are feasible for S $(\pi(q^S) \geqq 0)$ for any feasible choice of prices for the coalition $N-S$. If the coalition S chooses prices in V^S, then it is not feasible for the coalition $N-S$ to choose prices which would cause negative profits for S. Thus, V^S represents prices the coalition S can obtain unilaterally, with no cooperation from members of $N-S$.

If the prices of the enterprise lay in the interior of V^S, for some $S \subset N$, then the coalition S could choose prices in V^S which were uniformly lower than the given prices, and furthermore unilaterally change the supply structure to realize the lower prices (since those prices are in V^S). Clearly, core prices should be in V^N but not V^S; hence,

$$(6) \qquad Core = V^N - \bigcup_S V^S$$

To illustrate what can occur in a game with nonzero cross-elasticities, we develop and extend a simple two-service example given by Zajac. This enables us to examine (a) the core of the game, (b) what happens if either service opts to leave (the "noncooperative" game), and (c) how the core of this game corresponds to the core of the fixed demand game.

Suppose we have a firm producing two commodities with \$10 in common fixed cost. Commodity 1 is produced with \$10 allocable fixed cost and a constant marginal of \$1. Commodity 2 requires \$60 of allocable fixed cost and a constant marginal cost of \$0.50. Thus

$$\begin{aligned} (7) \qquad C(q_1, 0) &= 20 + q_1 \\ C(0, q_2) &= 70 + .5q_2 \\ C(q_1, q_2) &= 80 + q_1 + .5q_2 \end{aligned}$$

The two goods are substitutes with linear demand functions over the relevant range given by:

$$\begin{aligned} (8) \qquad q_1 &= 100 - 10p_1 + 4p_2 \\ q_2 &= 40 + 4p_1 - 4p_2 \end{aligned}$$

where p_i is the price of commodity i. The profit function of the firm is denoted by $\pi(p_1, p_2)$ which is assumed constrained to zero, so that $V^{\{1,2\}}$ is the set of prices satisfying

$$\begin{aligned} (9) \qquad \pi(p_1, p_2) = &- 10p_1^2 + 8p_1p_2 - 4p_2^2 \\ &+ 108p_1 + 38p_2 - 200 = 0 \end{aligned}$$

This second-degree equation plots as an ellipse in (p_1, p_2) space. Only the lower left-hand portion of this ellipse is relevant, corresponding to our assumption that $\partial\pi/\partial p_i > 0$ (see footnote 14).

What happens if the two commodities are produced separately by two different firms? Each firm would have its own profit function π_i which would reflect the duplicated common costs, and would also depend upon the prices that the other firm would charge, because of the nonzero cross-elasticities. Hence,

---

[18] This approach was suggested to me by my colleague William Sharkey.

$$(10)\quad \begin{aligned} \pi_1(p_1, p_2) &= -10p_1^2 + 4p_1p_2 + 110p_1 \\ &\quad - 4p_2 - 120 = 0 \\ \pi_2(p_1, p_2) &= -4p_2^2 + 4p_1p_2 + 42p_2 \\ &\quad - 2p_1 - 70 = 0 \end{aligned}$$

In Figure 1, we show the curves $\pi=0$, $\pi_1=0$, and $\pi_2=0$ plotted in (p_1, p_2) space. It can be seen that

$$\begin{aligned} V^1 &= \{p_1 \mid p_1 \geqq p_1^* = \$1.204\} \\ V^2 &= \{p_2 \mid p_2 \geqq p_2^* = \$2.51\} \end{aligned}$$

In fact, p_1^* and p_2^* are the minimax prices of the noncooperative game, so that point $C=(p_1^*, p_2^*)$ is the solution to that game. Further, p_1^*, p_2^* is a solution to the simultaneous system (10), and the only one for which $\partial\pi_i/\partial p_i>0$.

The core of the game consists of the set of prices satisfying

$$\pi(p_1, p_2) = 0 \qquad p_1 \leqq p_1^* \qquad p_2 \leqq p_2^*$$

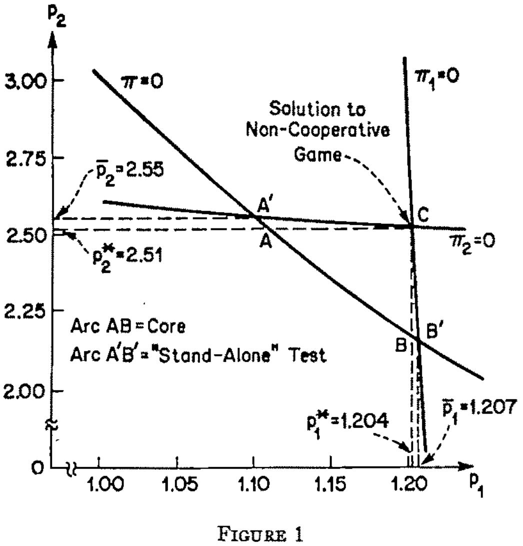

FIGURE 1

which is the arc AB in Figure 1.

Figure 1 also yields an interesting interpretation of the fixed demand (zero cross-elasticities) game. Suppose the prices lie on the curve $\pi=0$ but are to the right of $\pi_1=0$. Then $\pi_1>0$ and the revenues from commodity 1 exceed its stand-alone cost and thus do not lie in the core of the fixed demand game. Similarly, if the prices satisfied $\pi=0$ but lie above $\pi_2=0$, then the revenues from commodity 2 exceed its stand-alone cost, and are not in the core. The fixed demand core is the arc $A'B'$ in Figure 1, for which $p_1 \leqq \bar{p}_1 = \$1.207$ and $p_2 \leqq \bar{p}_2 = \$2.55$. This corroborates our previous assertion that the arc is smaller if we introduce positive cross-partials in the demand function. Thus, if the commodities in question are substitutes, there may be prices which pass an incremental cost test and yet involve cross-subsidy.

IV. Summary

In this paper, we have defined and analyzed the issues of cross-subsidization in enterprises with economies of joint production. We have couched the problem in game theoretic terms, which led us to note that not only individual commodities must be examined for possible cross-subsidization, but also groups of commodities ("coalitions"). We then explored the question of market incentives under subsidizing vs. subsidy-free prices, and noted that subsidization by prices in a free market would lead to competitive entry and instability of the joint enterprise, particularly when no subsidy-free prices existed. The discussion of the relationship between welfare-maximizing prices and subsidy-free prices suggested conditions under which these two criteria might clash, and the necessity of coercive intervention in restricting market entry if that were the case. This extension of a game theoretic analysis to the case of nonzero cross-elasticities indicates how the problem might be approached, and what difficulties might be encountered.

Revealed Preference for Public Goods

By HAJIME HORI*

The most serious problem for the modern theory of optimal public expenditure is that although it has to be based on some social welfare function, individual preferences for public goods, which constitute the elements of any individualistic social welfare function, are hard to assess. It is argued that since every individual can freely participate in the consumption of a public good, there is an incentive for him to either underreport or overreport his preferences depending on how the reported preferences are used in the financing process of the public good.[1]

This argument will be correct if an individual's preferences for public goods can be expressed only directly. In many cases, however, the consumption of a public good has some technical or objective relationship with the consumption of some private goods. Thus, the benefit an individual derives from free highways depends on how much he spends on a car and gasoline. Even the benefit an individual derives from the judicial system depends on how much he spends to hire the services of lawyers. Also, an individual can enjoy the same security police provide by hiring private guards and installing locks, and so on. In these cases, if we know the technical relationships between the consumption of private goods and the consumption of public goods, then from the market data relating the amounts of private goods bought to prices and the data on the existing amounts of public goods, we might be able to infer (i) the amounts of *final goods* consumed (say the number of trips from one point to another, the degree of justice, the security from robbery, etc.), and (ii) their opportunity costs which the individual was willing to pay. But if we succeed in this inference, then all that remains to be done in order to find the individual's utility function will be to integrate back the relationship between the amounts of final goods consumed and their opportunity costs.

A trivial example can be provided by assuming that each public good is perfectly substitutable with a private good. Let y_i be the quantity of the ith public good and x_i be the quantity of a private good which is a perfect substitute for the ith public good. Then the benefit derived from the ith public good and its perfect substitute can be measured by x_i+y_i. Suppose we have ascertained an individual consumer's demand functions for private good when all the y_i are zero. We know from the revealed preference theory that if these demand functions satisfy a certain condition (namely the symmetry of the Slutsky matrix), then there exists a utility function unique up to a monotone transformation:

$$U = U(x_1, x_2, \ldots, x_n)$$

But since the ith private good is a perfect substitute for the ith public good, this consumer's utility function which covers the case where $y_i \neq 0$ is given by

---

* Assistant professor of economics, Tohoku University, Sendai, Japan. Much of the work for this paper was completed at Tulane University. I am indebted to an anonymous referee for useful suggestions and comments.

[1] See Richard Musgrave, Paul Samuelson (1964), and Hirofumi Shibata. The devices recently developed by Mordecai Kurz for determining the demand for public goods also accept this argument and try to establish environments in which there is no incentive for consumers to falsify their preferences.

$$V(x_1, \ldots, x_n; y_1, \ldots, y_n) = U(x_1 + y_1, x_2 + y_2, \ldots, x_n + y_n)$$

Admittedly this example is trivial. But, as will be shown below, a similar reasoning can be extended to more general situations. What is crucial is *the assumption that there exists a technical or objective relationship between the consumption of each public good and the consumption of some private goods.*

I

In order to formalize this assumption, suppose an individual's utility function is of the Strotz–Lancaster–Muth–Sandmo type,[2] and let its general representation be

$$(1) \qquad U = U(z) = U(z_1, z_2, \ldots, z_n)$$

where the z_i are the amounts of final goods consumed and $z=(z_1, \ldots, z_n)$. Each z_i is related to the amounts of private and public goods used according to the formula

$$(2) \qquad z_i = f^i(x^i; y_i), \qquad i = 1, \ldots, n$$

where x^i is the vector of the quantities of private goods and y_i is the quantity of a public good used for the production (within household) of the ith final good. Here we are assuming for simplicity that the production of each final good requires at most one public good but the extension to the case of more than one public good per final good is straightforward. *The household production technology* (or consumption technology) represented by the functions f^i, $i=1, \ldots, n$, is assumed to be common to every consumer. We also assume sufficient smoothness of the functions f^i.

Our purpose is to consider under what conditions we can deduce the specific form of the utility function (1), assuming that we know the objective household production technology (2) and the individual consumer's market behavior summarized by his demand functions for private goods,

$$(3) \qquad x_j = x_j(p, I, y)$$

where x_j is the quantity demanded of the jth private good, p is the price vector of private goods, I is income, and y is the vector of the supplies of public goods.

As was mentioned before, the main task is to find the marginal rate of substitution between each pair of final goods at each point in the final-goods space. But the specific exercises we have to go through for this purpose depend upon how private goods enter the household production of final goods. We will separately consider four possible forms of the household production technology, which differ from each other by the way private goods enter the household production process.

The first form of household production technology to be considered is *separable* in the sense that each private good enters the production of only one final good. Thus let

$$(4) \qquad z_i = f^i(x_{m_{i-1}+1}, x_{m_{i-1}+2}, \ldots, x_{m_i}; y_i), \qquad i = 1, \ldots, n$$

where $m_0=0$. There are assumed to be $m_n=m$ private goods, out of which $m_{i-1}+1, \ldots, m_i$ are used for the production of the ith final good. This form of household production function was considered by Strotz and Muth. We will take up this household production technology in Section II.

The second form to be considered is the one in which each private good is *divided* into multiple uses. For example, one's leisure time is divided into several distinct uses such as reading novels, camping in a national park, and so on. Let x_{ij} denote the amount of the jth private good used in the production of the ith final good. If there are m private goods, then we can write:

---

[2] See Robert Strotz, Kelvin Lancaster, Richard Muth, and Agnar Sandmo. It was Sandmo who first applied this type of utility function to the analysis of optimal public expenditure.

$$(5) \qquad z_i = f^i(x_{i1}, x_{i2}, \ldots, x_{im}; y_i), \qquad i = 1, \ldots, n$$

Although this can be regarded as a generalization of (4), a complication arises because each x_{ij} cannot usually be observed in the market; for each price-income-public goods combination, what we can observe in the market is the *total quantity* consumed of each private good, $x_j = \sum_{i=1}^{n} x_{ij}$, and not its decomposition x_{ij}. We will consider this form of household production technology in Sections III and IV.

The third form of the household production technology is that of *assumed indivisibility* (or joint production). Namely, the use of private goods $x_1, \ldots, x_m$ in the production of one final good necessarily contributes to the production of other final goods and it is impossible to measure how much of x_1, say, goes into the production of z_1 or z_2 or z_3 and so on. Thus this form of household production technology can be represented by

$$(6) \qquad z_i = f^i(x_1, x_2, \ldots, x_m; y_i), \qquad i = 1, \ldots, n$$

This can be regarded as another generalization of (4). Some properties of consumer behavior which incorporate this type of household production technology were considered by Lancaster under an additional assumption that the functions f^i are linear.[3] We will consider this household production technology in Sections V and VI.

The final form to be considered is a mixture of (5) and (6) and can be written as

$$(7) \quad z_i = f^i(x_{i1}, \ldots, x_{im}; x_{m+1}, \ldots, x_M; y_i), \qquad i = 1, \ldots, n$$

where each of the private goods 1 through m is divided into various distinct uses while each of the private goods $m+1$ through M enters the production of various final goods jointly. We will consider this household production technology in Sections VII and VIII.

II

Let us start with the simplest case where each private good enters the household production of only one final good:

$$(4) \quad z_i = f^i(x_{m_{i-1}+1}, \ldots, x_{m_i}; y_i), \qquad i = 1, \ldots, n, \ m_0 = 0, \ m_n = m$$

In this case we can in principle observe m distinct demand functions

$$(8) \quad x_j = x_j(p, I, y), \quad j = 1, \ldots, m$$

where $p = (p_1, \ldots, p_{m_1}, p_{m_1+1}, \ldots, p_m)$. By substituting (8) in (4), we can find what z_i our consumer chooses for each combination of prices, income, and public goods:

$$(9) \quad \bar{z}_i = f^i(x(p, I, y)), \quad i = 1, \ldots, n$$

In order to evaluate the marginal rates of substitution between final goods, we first define the cost function for each final good by

$$(10) \quad C_i(z_i; p, y_i) = \min \left\{ \sum_{j=m_{i-1}+1}^{m_i} p_j x_j \;\middle|\; f^i(x_{m_{i-1}+1}, \ldots, x_{m_i}; y_i) = z_i \right\}, \qquad i = 1, \ldots, n$$

Note that these cost functions are common to every individual. The budget constraint for an individual with income I, defined in the final-goods space, is given by

$$(11) \qquad \sum_{i=1}^{n} C_i(z_i; p, y_i) = I$$

A rational consumer will maximize his utility subject to the budget constraint (11). Thus the combination of final goods he chooses, given by (9), satisfies (11).

---

[3] The linearity of the functions f^i, however, poses a problem to our approach, as will be shown in Section V.

Moreover, at point $\bar{z}=(\bar{z}_1, \ldots, \bar{z}_n)$ given by (9), the budget surface must be tangent to one of his indifference surfaces. Thus, if we let $R_{ii'}(z)$ denote the marginal rate of substitution between the ith and the i'th final goods at point z, we obtain

$$R_{ii'}(\bar{z}) = -\frac{C_i'(\bar{z}_i)}{C_{i'}'(\bar{z}_{i'})}, \quad i, i' = 1, \ldots, n, \quad i \neq i' \tag{12}$$

If the range of the demand functions for final goods (9) is equal to the whole final-goods space, then we can obtain the marginal rates of substitution for all the points from (12).

III

Next we consider the case where each private good is divided into multiple uses:

$$z_i = f^i(x_{i1}, x_{i2}, \ldots, x_{im}; y_i), \quad i = 1, \ldots, n \tag{5}$$

Analogously to equations (10) and (11) in the previous section, we can find the cost functions and the budget constraint from (5). But in the present case, this is not enough for finding the marginal rates of substitution. Since the available market data in the present case take the form of m demand functions

$$\sum_{i=1}^{n} x_{ij} \equiv x_j = x_j(p, I; y), \quad j = 1, \ldots, m \tag{13}$$

which relate p, I, and y to the total quantities x_j and not to their decompositions x_{ij}, we cannot directly relate p, I, and y to z, and therefore we cannot directly pinpoint at what point in the final-goods space the budget surface is tangent to an indifference surface.

In order to find the z which the consumer has in mind when he buys $x=(x_1, \ldots, x_m)$ according to (13), let us consider the problem:

$$\text{Minimize } \sum_{j=1}^{m} p_j x_j \text{ over } x \tag{14}$$

subject to $f^i(x_{i1}, \ldots, x_{im}; y_i) = z_i$, $i = 1, \ldots, n$,

$$\sum_{i=1}^{n} x_{ij} = x_j, \quad j = 1, \ldots, m$$

for each z. This is an objective part of our consumer's utility maximization and has a unique solution

$$x_{ij} = g_{ij}(z_i; p, y_i), \quad i = 1, \ldots, n, \quad j = 1, \ldots, m \tag{15}$$

$$x_j = g_j(z; p, y) \equiv \sum_{i=1}^{n} g_{ij}(z_i; p, y_i), \quad j = 1, \ldots, m$$

if the household production functions f^i are concave-contoured (i.e., if their isoquants are convex toward the origin) in the m-dimensional private-goods space.

Equations (15) immediately give the cost functions

$$C_i(z_i; p, y_i) \equiv \sum_{j=1}^{m} p_j g_{ij}(z_i; p, y_i), \quad i = 1, \ldots, n \tag{16}$$

and the budget constraint by (11) and (16). At the same time, note that since the demand functions (13) are the result of the consumer's utility maximization, they must be consistent with (15). Thus the z which the consumer has in mind when he buys $x=(x_1, \ldots, x_m)$ according to (13) must satisfy

$$g_j(z; p, y) = x_j(p, I; y), \quad j = 1, \ldots, m \tag{17}$$

for each combination of p, I, and y. In (17), we have m equations for n unknowns z_i and the preference orderings of the consumer appear as the observable demand functions on the right-hand side. This system of equations has at least one solution z if the consumer is consistent. But for observers, the crucial question is the uniqueness of a solution. If (17) has multiple solutions, then we cannot tell at what z the budget surface (11) is tangent to an indifference surface and therefore there is no way of finding the structure of the indifference map. If a solution is unique for a sufficient number of combinations of p, I, and y so that we can cover the whole final-goods space by varying p, I, and y in

$$z_i = z_i(p, I, y), \qquad i = 1, \dots, n \tag{18}$$

then, in the same way as in the previous section, we will be able to arrive at the marginal rates of substitution between final goods as functions of z, given by (12).

There is another way of formulating the problem. For each $x = (x_1, \dots, x_m)$, consider

$$\text{(19)} \quad \text{Maximize } \sum_{i=1}^{n} C_i(z_i; p, y_i) \text{ over } z$$

$$\text{subject to } z_i = f^i(x_{i1}, \dots, x_{im}; y_i), \qquad i = 1, \dots, n$$

$$\sum_{i=1}^{n} x_{ij} = x_j, \qquad j = 1, \dots, m$$

where the functions $C_i(z_i; p, y_i)$ are defined by (16). Obviously (19) is a dual to the cost minimization problem (14). Therefore the uniqueness of a solution to (17) is equivalent to the uniqueness of a solution $z_i = z_i(p, I, y)$ of (19) for each $x = x(p, I, y)$ given by (13).

We have formulated the problem of finding the chosen z in two equivalent ways, namely as the problem of the uniqueness of a solution to either (17) or (19). The first formulation is probably better suited to formal analysis while the second formulation admits of a geometrical analysis.

Equations (17) immediately show that the uniqueness requires $m \geqq n$. The case where $m > n$ can be reduced to the case of $m = n$ because the rationality of the consumer implies the existence of a solution to (17) and therefore all we have to do is to pick a suitable set of n equations and consider the uniqueness for it. For the case where $m = n$, the problem of the uniqueness of a solution to equations similar to (17) has been considered in a different context and some sufficient conditions are known. Interested readers are referred to David Gale and H. Nikaido, and Nikaido.[4]

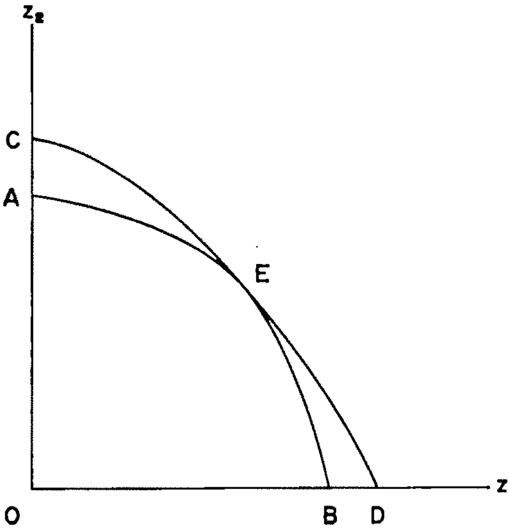

FIGURE 1

Figures 1 and 2 illustrate the uniqueness problem as formulated in (19). The curves AEB in Figure 1 and $AEE'B$ in Figure 2 are the possibility frontier; namely the frontier of the set of all the z satisfying

---

[4] If the $f^i(x_{i1}, \dots, x_{im}; y_i)$, $i = 1, \dots, n$, are linearly homogeneous in private goods $x_{i1}, \dots, x_{im}$, then the most refined sufficient condition for the uniqueness of a solution, developed by I. F. Pearce in the context of the factor-price-equalization theorem, can be utilized. If we let $x^i(p; y_i)$ denote the m-dimensional vector of the minimum-unit-cost inputs for the ith final good, then (17) or (19) has a unique solution if the n vectors $x^i(p; y_i)$ are linearly independent for each p. See Pearce (1959, 1967) and Samuelson (1967). In the present context, however, we cannot usually expect the linear homogeneity in private goods alone of the household production functions. The sufficient conditions developed by Gale and Nikaido, and Nikaido do not depend on the homogeneity assumption.

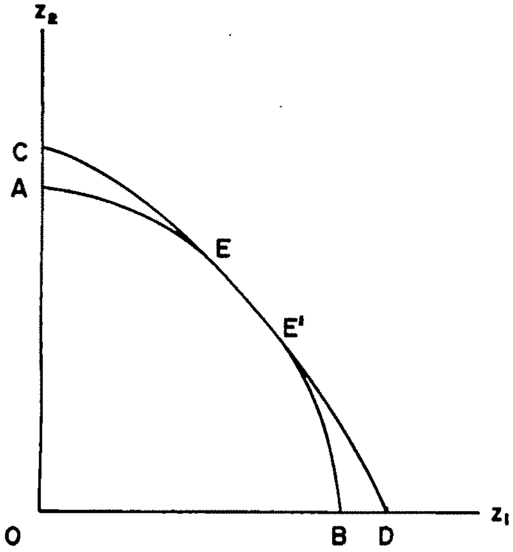

FIGURE 2

$$z_i = f^i(x_{i1}, \ldots, x_{im}; y_i), \qquad i = 1, 2$$
$$x_{1j} + x_{2j} = x_j, \qquad j = 1, \ldots, m$$

for the x actually bought at some p, I, and y. The curves *CED* in Figure 1 and *CEE'D* in Figure 2 are the budget curve that corresponds to the maximum total cost obtainable on the possibility frontier when the prices of private goods and the supplies of public goods are p and y. A rational consumer will choose the z at which the budget curve is tangent to an indifference curve. At this z the possibility frontier will also be tangent to the same indifference curve because, in addition to choosing an x, the consumer has to divide each x_j into x_{1j} and x_{2j} so as to maximize his utility. Thus at the z which the consumer has in mind in buying an x, the budget curve and the possibility frontier are tangent to each other.

Figure 1 depicts the case of a unique solution and Figure 2 the case of multiple solutions. In Figure 2, we know that an indifference curve must be tangent to both the budget curve and the possibility frontier at some point between E and E'. But from our data we cannot tell which point it is.

IV

Since the uniqueness of a solution to (17) or (19) is crucial, it will be worthwhile to consider this problem further, using a simple example. In this section, we will assume that the household production functions are of the Cobb-Douglas type.

Let

$$(20) \qquad z_i = y_i^{b_i} \prod_{j=1}^{m} x_{ij}^{a_{ij}}, \qquad i = 1, \ldots, n$$

$$\text{where} \quad 0 \leq a_{ij}, \qquad i = 1, \ldots, n, \quad j = 1, \ldots, m$$
$$0 < \sum_{j=1}^{m} a_{ij}, \qquad i = 1, \ldots, n$$
$$0 \leq b_i, \qquad i = 1, \ldots, n$$

In this case, equations (17) become

$$(21) \qquad \sum_{i=1}^{n} h_{ij} z_i^{1/a_i} = x_j(p, I; y), \qquad j = 1, \ldots, m$$

where

$$h_{ij} = y_i^{-bi/a_i} \frac{a_{ij}}{p_j} \prod_{l=1}^{m} \left(\frac{p_l}{a_{il}}\right)^{a_{il}/a_i}$$
$$i = 1, \ldots, n, \quad j = 1, \ldots, m$$
$$a_i = \sum_{j=1}^{m} a_{ij}, \qquad i = 1, \ldots, n$$

Assume that $m = n$. Then a solution to (21) is unique if and only if

$$\begin{vmatrix} h_{11} & \ldots & h_{n1} \\ \vdots & & \vdots \\ h_{1n} & & h_{nn} \end{vmatrix} \neq 0$$

But it is easy to check that

$$\begin{vmatrix} h_{11} & \ldots & h_{n1} \\ \vdots & & \vdots \\ h_{1n} & \ldots & h_{nn} \end{vmatrix} = \prod_{i=1}^{n} w_i \prod_{j=1}^{n} \frac{1}{p_j} \begin{vmatrix} a_{11} & \ldots & a_{n1} \\ \vdots & & \vdots \\ a_{1n} & \ldots & a_{nn} \end{vmatrix}$$

where

$$w_i = y_i^{-b_i/a_i} \prod_{j=1}^{n} \left(\frac{p_i}{a_{ij}}\right)^{a_{ij}/a_i}, \quad i = 1, \ldots, n$$

Therefore the system of equations (21) has a unique solution if and only if $|a_{ij}| \neq 0$. Including the case where $m>n$, we can conclude that (21) has a unique solution if and only if the n vectors of constants

$$\begin{bmatrix} a_{i1} \\ a_{i2} \\ \cdot \\ \cdot \\ \cdot \\ a_{im} \end{bmatrix}, \quad i = 1, \ldots, n$$

are linearly independent.

V

The third form of the household production technology to be considered is that of *assumed indivisibility* (or joint production). The production of a final good with the use of private goods $x_1, \ldots, x_m$ (and the public good y_i) is necessarily accompanied by the production of other final goods:

$$(6) \qquad z_i = f^i(x_1, x_2, \ldots, x_m; y_i), \quad i = 1, \ldots, n$$

Unlike the second case considered above, to find the combination of final goods chosen by an individual poses no problem, because all the arguments of each household production function are observable variables. Let

$$(22) \quad B(p, I, y) = \left\{ z \,\middle|\, z_i \leq f^i(x_1, \ldots, x_m; y_i), \; i=1, \ldots, n, \; \sum_{j=1}^{m} p_j x_j = I \right\}$$

$B(p, I, y)$ is the set of all the z the individual can obtain when the prices of private goods, income, and the quantities of public goods are p, I, and y. The frontier of this set gives the budget surface on which the chosen z has to lie. Let

$$(23) \qquad F(z_1, \ldots, z_n; p, I, y) = 0$$

denote this surface. If $\bar{x}$ is the chosen vector of private goods, we can find the chosen vector of final goods, denoted by $\bar{z}$, from equations (6). Then one of the indifference surfaces must be tangent to (23) at $\bar{z}$. Thus *if the budget surface* (23) *is differentiable*, then the marginal rate of substitution between the ith and i'th final goods at $\bar{z}$ is given by

$$(24) \quad R_{i,i'}(\bar{z}) = -\frac{\partial F(\bar{z}; p, I, y)/\partial z_i}{\partial F(\bar{z}; p, I, y)/\partial z_{i'}}, \quad i, i' = 1, \ldots, n, \quad i \neq i'$$

The function F, however, is not necessarily differentiable, even if the functions f^i are differentiable, as shown in Figures 3 to 5. Figure 3 depicts the case where there are two final goods but only one private good. As the amount of the private good is increased, the obtainable combination of z_1 and z_2 moves along the curve *ODB*. Given the price of the private good, income, and the amounts of public goods, there is only one relevant combination of z_1 and z_2, represented by point *B*. The

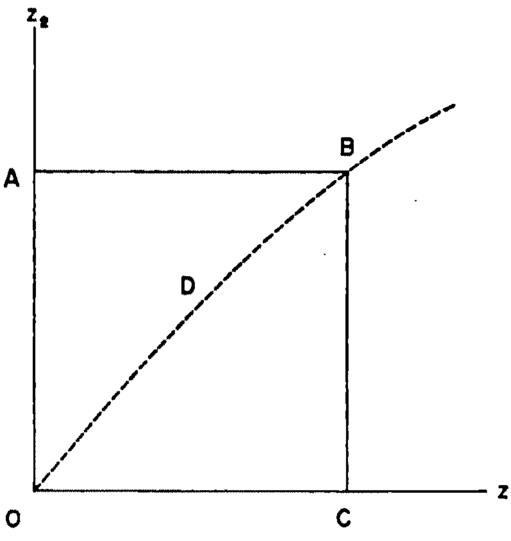

FIGURE 3

budget curve is ABC, and any rational individual will choose point B. Utility maximization at point B is consistent with an infinite variety of marginal rates of substitution. This situation is apparently due to the fact that the consumer does not have a choice among different combinations of z_1 and z_2 since there is only one choice variable. Generalization to the case of more final goods and more private goods is immediate. Thus, in order to avoid this situation, we have to require that

$$m \geq n \tag{25}$$

Figure 4 represents the case where the household production technology is linear in x_1, x_2, and y:

$$z_1 = b_{11}x_1 + b_{12}x_2 + c_1y_1$$
$$z_2 = b_{21}x_1 + b_{22}x_2 + c_2y_2$$

The ray EB starting at E is the locus of all the z obtainable from private good 1 alone, and the ray EC starting at E is the locus of all the z obtainable from private good 2 alone. Thus points B and C denote the combinations of z_1 and z_2 obtainable when all the income is spent on private goods 1 and 2, respectively. The budget surface $ABCD$ has kinks at B and C because of the nonnegativity constraint $x_j \geq 0$, $j = 1, 2$. Again in this case, if the chosen combination of x_1 and x_2 corresponds to point B or point C (which is quite likely), we cannot infer the marginal rate of substitution between final goods 1 and 2.

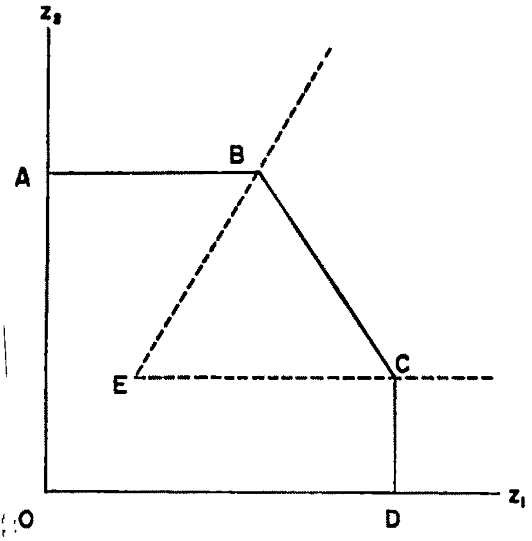

Figure 4

In Figure 4 the kinks of the budget curve are due to the *effective* nonnegativity constraint. Thus, for each $i = 1, \ldots, n$, let

$$J_i = \left\{ j \,\middle|\, \frac{\partial f^i}{\partial x_j} \neq 0,\ x_j = 0 \right\}$$

$$v^i = (v^i_1, \ldots, v^i_m), \qquad v^i_j > 0 \qquad \text{for } j \in J_i$$

If the household production functions have the property that

$$\lim_{h\to 0} \frac{d}{dh} f^i(x + hv^i; y_i) = \lim_{h\to 0} \sum_{j=1}^{m} \frac{\partial}{\partial x_j} f^i(x + hv^i; y_i)\cdot v^i_j = \infty, \qquad i = 1, \ldots, n \tag{26}$$

then the budget surface will not show this type of kink.

There is one more source of nondifferentiability. Suppose $n = m = 2$, and for each $i = 1, 2$, consider

$$\text{Maximize } z_i = f^i(x_1, x_2, y_i)$$

$$\text{subject to} \qquad p_1x_1 + p_2x_2 = I$$

Let $x^i = (x^i_1, x^i_2)$ denote the optimum vector for the ith maximization problem, $i = 1, 2$, and let

$$z^i_1 = f^1(x^i; y_i)$$
$$z^i_2 = f^2(x^i; y_i)$$
$$z^i = (z^i_1, z^i_2), \qquad i = 1, 2$$

If $z^1 = z^2$, then there is no tradeoff between the productions of final goods 1 and 2, as is shown in Figure 5. In Figure 5 as x_1 is increased from zero and x_2 is decreased from I/p_2 subject to $p_1x_1 + p_2x_2 = I$, both z_1

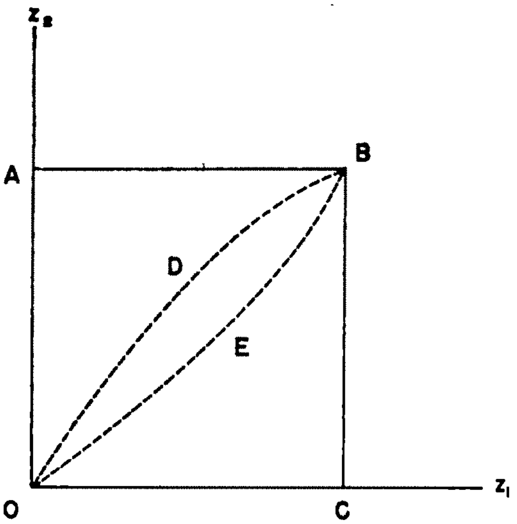

FIGURE 5

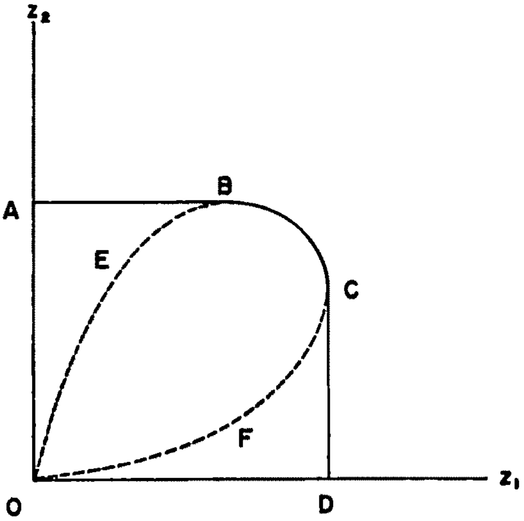

FIGURE 6

and z_2 increase along the curve *ODB* and reach their maxima simultaneously at point *B*. As x_1 is further increased and x_2 is further decreased, both z_1 and z_2 decrease. As a result, the budget curve is given by *ABC* with a kink at *B*. In this case, every rational consumer will choose point *B*, and again it is impossible to find the marginal rate of substitution between z_1 and z_2.

Figure 6 gives a smooth budget curve which results if $z^1 \neq z^2$. Point *B* corresponds to vector z^2 and point *C* corresponds to vector z^1. As x_1 is increased from zero and x_2 decreased from I/p_2, both z_1 and z_2 increase and z_2 reaches its maximum at point *B*. If x_1 is further increased and x_2 further decreased, z_2 decreases but z_1 increases until z_1 reaches its maximum at point *C*. After that, both z_1 and z_2 decrease along *CFO*.

In order to have a smooth budget surface in the general case of n final goods and m private goods with $m \geq n$, it will be necessary (and sufficient together with (25) and (26)) to have a smooth budget curve like Figure 6 on each 2-dimensional slice of the n-dimensional final-goods space. Thus, for each pair of final goods i_1 and i_2, define an $(n-2)$-dimensional vector $z^{i_1 i_2}$ by

$$z^{i_1 i_2} = (z_1, z_2, \dots, z_{i_1-1}, z_{i_1+1}, \dots, z_{i_2-1}, z_{i_2+1}, \dots, z_n)$$

For $i = i_1$ and $i = i_2$, consider

$$\text{(27)} \quad \text{Maximize} \quad z_i = f^i(x_1, \dots, x_m; y_i)$$

$$\text{subject to} \qquad \sum_{j=1}^{m} p_j x_j = I,$$

$$f^k(x_1, \dots, x_m; y_k) = z_k, \qquad k \neq i_1, i_2$$

Let x^i denote the optimum vector of x for the ith maximization problem and let

$$\overset{i}{z}_k = f^k(\overset{i}{x}; y_k)$$

$$\overset{i}{z} = (\overset{i}{z}_1, \overset{i}{z}_2, \dots, \overset{i}{z}_n), \qquad k = 1, \dots, n; \quad i = i_1, i_2$$

Both z^{i_1} and z^{i_2} are functions of $z^{i_1 i_2}$ (and p, I^*, y). Thus the condition for the smoothness of the budget surface for given p, I, and y is given by

$$\text{(28)} \quad z^{i_1} \neq z^{i_2} \quad \text{for all } z^{i_1 i_2}, i_1, i_2 = 1, \dots, n, \quad i_1 \neq i_2$$

Conditions (25), (26), and (28) constitute sufficient conditions for the existence of a smooth budget surface.

VI

As an example, suppose that the household production functions are of the Cobb-Douglas type:

$$(29)\quad f^i(x_1, \ldots, x_m; y_i) = y_i^{b_i} \prod_{j=1}^{m} x_j^{a_{ij}}, \qquad i = 1, \ldots, n$$

$$\text{where } 0 \leq a_{ij} < 1, \qquad i = 1, \ldots, n, \quad j = 1, \ldots, m$$

$$0 \leq b_i, \qquad i = 1, \ldots, n$$

$$\text{and} \quad n \leq m$$

The conditions (25) and (26) are satisfied. We will show that condition (28) is satisfied and the budget surface is smooth if

$$(30)\quad a^i = (a_{i1}, \ldots, a_{im}), \qquad i = 1, \ldots, n$$

are linearly independent.

In the following, we will take $i_1 = n-1$, $i_2 = n$. Also, we will number the goods and the constants in such a way that

$$(31)\quad \begin{vmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \vdots \\ a_{n1} & \cdots & a_{nn} \end{vmatrix} \neq 0$$

$$\Delta \equiv \begin{vmatrix} a_{11} & \cdots & a_{1,n-2} \\ \vdots & & \vdots \\ a_{n-2,1} & \cdots & a_{n-2,n-2} \end{vmatrix} \neq 0$$

Now the constrained maximization problems to determine x^{n-1}, z^{n-1}, x^n, and z^n are

$$\text{Maximize} \quad z_i = \prod_{j=1}^{m} x_j^{a_{ij}} y_i^{b_i}, \qquad i = n-1, n$$

$$\text{subject to} \quad \prod_{j=1}^{m} x_j^{a_{ij}} y_i^{b_i} = \bar{z}_i, \qquad i = 1, \ldots, n-2$$

$$\sum_{j=1}^{m} p_j x_j = I$$

For each of $i = n-1$, n, the first-order maximum conditions can be written as

$$(32)\quad \frac{p_k x_k \Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} p_j x_j a_{lk} \Delta_{lj}}{p_{n-1} x_{n-1} \Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} p_j x_j a_{l,n-1} \Delta_{lj}} = \frac{a_{ik}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{ij} a_{lk} \Delta_{lj}}{a_{i,n-1}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{ij} a_{l,n-1} \Delta_{lj}},$$

$$k = n, n+1, \ldots, m$$

where Δ_{lj} is the cofactor of a_{lj} in Δ.

Suppose $z^{n-1} = z^n$. Then there exists a vector $x = (x_1, \ldots, x_m)$ which satisfies the $(m-n+1)$ equations in (32) for both $i = n-1$ and $i = n$. Therefore, for each k, the right-hand side of (32) must have the same value for both $i = n-1$ and $i = n$. In particular, by taking $k = n$, we must have

$$\begin{aligned} (33)\quad B \equiv & \left(a_{nn}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{nj} a_{ln} \Delta_{lj}\right) \\ & \cdot \left(a_{n-1,n-1}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{n-1,j} a_{l,n-1} \Delta_{lj}\right) \\ & - \left(a_{n,n-1}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{nj} a_{l,n-1} \Delta_{lj}\right) \\ & \cdot \left(a_{n-1,n}\Delta - \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} a_{n-1,j} a_{ln} \Delta_{lj}\right) = 0 \end{aligned}$$

But it can be shown by using Sylvester's determinant identity that

$$(34)\quad B = \Delta \begin{vmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \vdots \\ a_{n1} & & a_{nn} \end{vmatrix}$$

Therefore, by (31), B cannot vanish. This completes the proof that if (30) holds then $z^{i_1} \neq z^{i_2}$, and therefore the budget surface is smooth.

VII

Finally let us consider a household production technology which is a mixture of the forms considered above:

$$(7) \quad z_i = f^i(x_{i1}, \ldots, x_{im}; x_{m+1}, \ldots, x_M; y_i), \quad i = 1, \ldots, n$$

where each of the private goods 1 through m is divided into different uses while each of the private goods $m+1$ through M enters the production of various final goods indivisibly. For each given p, I, and y, the market data we can use are the M quantities x_j, $j=1, \ldots, m, m+1, \ldots, M$, where

$$x_j = \sum_{i=1}^{n} x_{ij} \quad \text{for} \quad j = 1, \ldots, m$$

Thus, both of the problems we considered before are present: namely, (i) the nonsmoothness of the budget surface and (ii) the impossibility of finding the chosen vector z of final goods.

(i) As before, we will assume (26) in order to exclude the kinks of the budget surface arising from corner solutions. In the case of pure indivisibility, possible lack of tradeoffs between different final goods was another source of nonsmoothness. In the present case, however, if the household production of each final good requires at least one private good which is not used jointly, namely if

$$(35) \quad \frac{\partial f^i}{\partial x_{i,j_i}} \not\equiv 0 \quad \text{for some } j_i,\ 1 \leq j_i \leq m, \quad \text{and for each } i = 1, \ldots, n$$

then along the budget surface there always exists a tradeoff between each pair of final goods, and therefore the second source of nondifferentiability disappears. In fact, let $C(z)$ denote the minimum cost of acquiring z. Thus $C(z)$ is the solution to the problem:

$$(36) \quad \text{Minimize} \sum_{j=1}^{m} \sum_{i=1}^{n} p_j x_{ij} + \sum_{j=m+1}^{M} p_j x_j$$

$$\text{subject to } f^i(x_{i1}, \ldots, x_{im}; x_{m+1}, \ldots, x_M; y_i) = z_i, \quad i = 1, \ldots, n$$

Under assumptions (26) and (35), there exists a j_i for each i such that one of the necessary conditions for (36) is

$$p_{j_i} - \lambda_i \frac{\partial f^i}{\partial x_{i,j_i}} = 0$$

where λ_i is the Lagrangean multiplier for the ith constraint. As usual, λ_i gives the marginal cost of the ith final good and thus

$$\frac{\partial C}{\partial z_i} = \lambda_i = \frac{p_{j_i}}{\partial f^i / \partial x_{i,j_i}}, \quad i = 1, \ldots, n$$

are well defined and positive. Thus the budget surface

$$C(z) = I$$

is differentiable and its slope satisfies

$$\left. \frac{dz_i}{dz_{i'}} \right|_{C(z)=I} = -\frac{\partial C/\partial z_{i'}}{\partial C/\partial z_i} < 0, \quad i, i' = 1, \ldots, n, \quad i \neq i'$$

(ii) The problem of finding the chosen z takes a form slightly different from the one considered in Sections III and IV. Due to the assumed indivisibility, the minimization problem (36) may not give unique solutions for x_j, $j=m+1, \ldots, M$, even if the f^i have convex isoquants. In its stead, however, we can use the fact that the market data directly give the value of x_j, $j=m+1, \ldots, M$, for each p, I, and y. Let

$$\bar{x} = (x_{m+1}, \ldots, x_M)$$

For each $\bar{x}$ and z, consider the minimization problem (36) with respect to x_{ij}, $i=1, \ldots, n$, $j=1, \ldots, m$. If the f^i are concave-contoured in private goods, this will give a unique optimum solution

$$x_{ij} = g_{ij}(\bar{x}, z_i; p, y_i), \quad i = 1, \dots, n, \quad j = 1, \dots, m \tag{37}$$

Substitute (37) in (36) and perform the minimization, this time with respect to $\bar{x}$. This will give $M-m$ implicit equations

$$g_j(\bar{x}, z; p, y) = 0, \ j = m+1, \dots, M \tag{38}$$

The rationality of the consumer implies the consistency between (37) and (38) on the one hand and the M demand functions on the other in the following form:

$$\sum_{i=1}^{n} g_{ij}(\bar{x}(p, I; y), z_i; p, y_i) = x_j(p, I, y), \quad j = 1, \dots, m$$
$$g_j(\bar{x}(p, I; y), z; p, y) = 0, j = m+1, \dots, M \tag{39}$$

where $\bar{x}(p, I; y)$ is the vector of $M-m$ demand functions $x_j(p, I; y), j = m+1, \dots, M$. Thus the problem of finding the chosen z reduces to the unique solvability of (39) for z.

As in Section III, the uniqueness of an optimum z of the dual maximization problem

(40) Maximize

$$C(z; p, y) = \min\left\{ \sum_{j=1}^{m} \sum_{i=1}^{n} p_j x_{ji} + \sum_{j=m+1}^{M} p_j x_j \,\middle|\, f^i(x_{i1}, \dots, x_{im}, x_{m+1}, \dots, x_M; y_i) = z_i, \quad i = 1, \dots, n \right\}$$

over z, subject to

$$z_i = f^i(x_{i1}, \dots, x_{im}, \bar{x}(p, I; y); y_i), \quad i = 1, \dots, n$$

$$\sum_{i=1}^{n} x_{ij} = x_j(p, I; y), \quad j = 1, \dots, m$$

is equivalent to the unique solvability of (39).

VIII

As an example, let us consider

$$z_i = \prod_{j=1}^{m} x_{ij}^{a_{ij}} \prod_{j=m+1}^{M} x_j^{a_{ij}} y_i^{b_i}, \ i = 1, \dots, n \tag{41}$$

where $a_{ij} \geqq 0$. For simplicity we assume that $a_{i1} > 0$ for $i = 1, \dots, n$. We will show that the linear independence of the n vectors

$$\begin{pmatrix} a_{i1} \\ a_{i2} \\ \cdot \\ \cdot \\ a_{iM} \end{pmatrix}, \quad i = 1, \dots, n$$

is necessary and sufficient for the unique solvability of (39). As before we can safely assume that $M = n$.

The first-order conditions for the minimization problem (36) under the assumption that the f^i are given by (41) can be arranged to yield

$$x_{ij} = \frac{p_1}{p_j} \frac{a_{ij}}{a_{i1}} x_{i1}, \qquad i = 1, \dots, n, \quad j = 1, \dots, m$$
$$x_j = \frac{p_1}{p_j} \sum_{i=1}^{n} \frac{a_{ij}}{a_{i1}} x_{i1}, \quad j = m+1, \dots, n \tag{42}$$

Let $\bar{x}_1, \dots, \bar{x}_n$ be the quantities of the n private goods bought. Then the x_{ij} and the x_j which correspond to the chosen z satisfy (39). Using (42), we obtain

$$\begin{pmatrix} a_{11} & a_{21} & \dots & a_{n1} \\ a_{12} & a_{22} & & a_{n2} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ a_{1n} & a_{2n} & \dots & a_{nn} \end{pmatrix} \begin{pmatrix} x_{11}/a_{11} \\ x_{21}/a_{21} \\ \cdot \\ \cdot \\ \cdot \\ x_{n1}/a_{n1} \end{pmatrix} = \begin{pmatrix} \bar{x}_1 \\ p_2\bar{x}_2/p_1 \\ \cdot \\ \cdot \\ \cdot \\ p_n\bar{x}_n/p_1 \end{pmatrix} \tag{43}$$

By assumption the coefficient matrix is nonsingular and therefore the x_{i1} are uniquely determined by the $\bar{x}_j$. Substituting the results in (42), we find the x_{ij} and x_j. Then from (41) we can find the z that uniquely corresponds to $\bar{x}$. Since equations (43) are linear in the x_{i1}, the linear independence of the n constant vectors is not only sufficient but also necessary.

IX

In order to see whether or not a consumer can be regarded to be revealing his preferences for public goods through his market behavior, we have considered in Sections II through VIII whether we can infer the marginal rates of substitution among final goods based on our knowledge concerning the household production technology and the demand functions for private goods for the following four types of household production technology:

(i) each private good is used in the production of only one final good;
(ii) each private good is divided into multiple distinct uses;
(iii) each private good contributes to the production of multiple final goods indivisibly;
(iv) mixture of (ii) and (iii).

Major results of our analysis may be summarized in the following way:

In case (i), sufficient smoothness of the household production functions are enough for the inference.

In case (ii), if the household production functions are concave-contoured in the private-goods space, then the problem reduces to the uniqueness of a solution to the system of equations (17) to which we can apply some sufficient conditions developed elsewhere. Or alternatively, the problem reduces to the uniqueness of the maximization problem (19).

In case (iii), the problem reduces to the differentiability of the budget surface defined in the final-goods space. Conditions (25), (26), and (28) are sufficient for this purpose.

In case (iv), if the production of each final good requires at least one private good which is not used in an indivisible fashion, and if the household production functions are concave-contoured in the private-goods space, then the problem reduces to the uniqueness of a solution to the system of equations (39) or the uniqueness of an optimum of the maximization problem (40).

Suppose we have found the marginal rate of substitution between each pair of final goods at every point in the n-dimensional final-goods space. The rest of the procedure for finding the utility function is familiar. Let

$$R_{i1}(z) \equiv R_i(z), \quad i = 2, 3, \dots, n$$

denote the marginal rate of substitution between the first and the ith final good at point z. Then the utility function can be obtained as a solution to the following total differential equation

$$dz_1 + R_2(z)dz_2 + R_3(z)dz_3 + \dots + R_n(z)dz_n = 0$$

This equation has a solution

$$U = U(z_1, z_2, \dots, z_n) \tag{44}$$

which is unique up to monotone transformation, if the $R_i(z)$ are continuously differentiable and satisfy the integrability conditions

$$\frac{\partial R_i}{\partial z_1} R_{i'} - \frac{\partial R_{i'}}{\partial z_1} R_i + \frac{\partial R_i}{\partial z_{i'}} - \frac{\partial R_{i'}}{\partial z_i} = 0, \qquad i, i' = 2, \dots, n$$

These integrability conditions are known to be satisfied if the consumer is rational in the sense that he has transitive preference orderings.[5] Finally, by substituting the relevant household production functions in (44), we arrive at the utility function which includes public goods as well as private goods as its arguments:

$$V(x, y) \equiv U(f^1(x^1, y_1), f^2(x^2; y_2), \dots, f^n(x^n; y_n)) \tag{45}$$

In concluding, we have to note the limitations of the present approach. First, the fundamental assumption that there exists and is known a household production technology is quite strong. Second, we have implicitly assumed that the consumer's market behavior honestly reflects his preference orderings. This may not be true if the consumer is aware that the information he conveys through his market behavior will be used in supplying and financing public goods. In this case his market behavior will show a change between the period when he is not aware of the possibility of the information being used and the period when he is. Thus there will arise an additional task of picking the right data. In spite of these limitations, it is hoped that the present approach will constitute a step toward putting the theory of optimal public expenditure on a more operational basis.

Market Equilibrium Versus Optimum in a Model with Congestion: Note

By Oded Hochman*

In their paper "Market Choice and Optimum City Size," Edwin Mills and David de Ferranti constructed a model of a city with congestion costs and derived the optimal land use pattern for it. However, they did not investigate the market equilibrium solution of their model and compare it to their optimal solution, as was done by Yitzhak Oron, David Pines, and Eytan Sheshinski.

In this paper the market equilibrium solution of the model is obtained and compared with the optimum solution derived by Mills and de Ferranti. It is shown that when congestion tolls are fully paid, market equilibrium is equivalent to optimality, as is the case in the paper by Oron et al. When no congestion tolls are paid, the city spreads further out than in the optimal case. The radius of the city increases, and land allocated to transportation at each location increases as well. Oron et al. were not able to obtain this result in their model.

Apart from the land use pattern, the average total cost of the urban economic activity in the model (housing and transportation) is investigated as a function of the population size. It is proved that average total cost and marginal total cost increase with population in the optimal case for any given population size. This result disproves the statement by Mills and de Ferranti that an optimum city size exists.

I. The Equilibrium Model

Mills and de Ferranti describe an optimization model of a town with congestion. Using their assumptions and notations, let u designate the distance from the center of the town. Then $L_1(u)$ is the land allocated to residential use at distance u, $L_2(u)$ the land allocated for transportation at distance u, and $T(u)$ the number of commuters crossing a circle of radius u. Let $p(u)$ be the cost per mile per commuter at distance u. Due to congestion this cost increases with the number of commuters $T(u)$ at distance u, and decreases with the land allocated for transportation, $L_2(u)$. We assume, following Mills and de Ferranti and William Vickrey, that it has the functional form as in equation (1).

$$p(u) = \bar{p} + \rho_1\left[\frac{T(u)}{L_2(u)}\right]^{\rho_2} \tag{1}$$

Let a_1 be the number of residents living on a unit of residential land. We assume a_1 to be constant. If $N(u)$ is the number of residents at distance u from the CBD, then

$$N(u) = a_1 L_1(u) \tag{2}$$

Let θ, $0 \leq \theta \leq 2\pi$ be the section of town, measured in radians, available for residential and transportation activities, then (3) follows immediately.

$$L_1(u) + L_2(u) = \theta u \tag{3}$$

$T(u)$, the number of commuters crossing a circle of radius u, is equal to the number of residents living outside this circle, hence

$$T(u) = \int_u^{\bar{u}} N(u)du \tag{4}$$

where $\bar{u}$ is the radius of the town.

The problem Mills and de Ferranti solved is the minimization of the total social cost TC associated with the residential and commuting activity, where TC is given in (5):

$$TC = \int_\epsilon^{\bar{u}} (p(u)T(u) + R_A\theta u)du \tag{5}$$

where ϵ, the radius of the CBD, and R_A, the agricultural land rent, are constants and exogenous given numbers.

---

* Department of economics and Center for Urban Studies, Tel-Aviv University.

The necessary condition for optimum is given by equation (6), (see (8) in Mills and de Ferranti):

$$
\frac{d\left[\dfrac{T(u)}{L_2(u)}\right]}{du} = -\frac{a_1}{\rho_2} - \frac{a_1\bar{p}}{\rho_1\rho_2(\rho_2+1)} \cdot \left[\frac{T(u)}{L_2(u)}\right]^{-\rho_2} \tag{6}
$$

We will now proceed to investigate the market equilibrium case. Let $R(u)$ be the equilibrium rent function and $C(u)$ the price an individual pays when he crosses a circle with radius u. The total housing and transportation cost of an individual located at distance u from the center is then:

$$
\int_0^u C(x)dx + a_1^{-1}R(u) \tag{7}
$$

where the first term expresses transportation cost and the second is the cost of the residential land. In this model no other costs are involved. This total cost of an individual should be the same everywhere under competitive equilibrium; otherwise, there will be excessive demand in some locations and no demand in others. Hence, by differentiating (7) with respect to u, we obtain

$$
C(u) + a_1^{-1}(dR(u)/du) = 0 \tag{8}
$$

A second condition is that land rents in each location be equal to the value of the marginal product of land in the transportation sector. The transportation product is the saving of costs rather than the production of positive income. The total value of transportation produced at location u is given by $(-T(u)p(u))$. The equality between the value of marginal product of land and rent is expressed in the following equation:

$$
R(u) = \partial(-T(u)p(u))/\partial L_2(u) \tag{9}
$$

This equation implies that transportation is produced efficiently even if its product is not necessarily sold in the market.

Substituting from (1) for $P(u)$ in the above equation and then differentiating, we get

$$
R(u) = \rho_1\rho_2(T(u)/L_2(u))^{\rho_2+1} \tag{10}
$$

We first assume that individuals pay full congestion tolls—i.e., each individual who passes through a circle with radius u pays an equal share of the rent of the land used for transportation at this radius. The total land used for transportation in radius u is $L_2(u)$, and the number of people crossing this circle is $T(u)$; hence, the equal share that each individual pays is $R(u)L_2(u)/T(u)$. Then $C(u)$ with full congestion tolls paid is:

$$
C_o(u) = p(u) + R(u)L_2^o(u)/T_o(u) \tag{11}
$$

where the index o indicates the case with congestion tolls. Substituting (11) into (8), and then substituting in it $R(u)$ from (10) and $dR(u)/du$ by differentiating (10), we get

$$
\frac{d\left[\dfrac{T_o(u)}{L_2^o(u)}\right]}{du} = -\frac{a_1}{\rho_2} - \frac{a_1\bar{p}}{\rho_1\rho_2(\rho_2+1)} \cdot \left[\frac{T_o(u)}{L_2^o(u)}\right]^{-\rho_2} \tag{12}
$$

But this is exactly equation (6) which is also equation (8) in Mills and de Ferranti. This means that the solution to the optimal problem solved by Mills and de Ferranti is also a solution to the case of market equilibrium with full congestion tolls.

Let us now assume that no congestion tolls are paid, i.e.,

$$
C_e(u) = p(u) \tag{13}
$$

where e indicates the case without congestion tolls. We still assume efficiency in transportation production; i.e., (9) and (10) are still valid. If we substitute (13) into (8) and substitute for $dR(u)/du$ from (10) and for $p(u)$ from (1), we get

$$
\frac{dy_e}{du} = -\frac{a_1}{\rho_2(\rho_2+1)} - \frac{a_1\bar{p}}{\rho_1\rho_2(\rho_2+1)}\, y_e^{-\rho_2} \tag{14}
$$

where:

$$y = T(u)/L_2(u) \tag{15}$$

and y_e is y in the case with no congestion tolls.

We will now try to compare characteristics of the town with congestion tolls to those of the town without congestion tolls. By setting $R(\bar{u}) = R_A$ in (10), we get:

$$y_o(\bar{u}_o) = y_e(\bar{u}_e) \tag{16}$$

From (12) and (14) we learn that the decline in $y_o(u)$ when u decreases is greater than in $y_e(u)$; i.e., y_o increases more rapidly with $(\bar{u}-x)$ than y_e. Hence, for any given distance from the boundary of the city x,

$$y_o(\bar{u} - x) > y_e(\bar{u} - x)$$

This means that at the distance x from the boundary of town,

$$T_o(\bar{u}_o - x)/L_2^o(\bar{u}_o - x) > T_e(\bar{u}_e - x)/L_2^e(\bar{u}_e - x)$$

This implies that at least one of the following relations must always be fulfilled.

$$T_e(\bar{u}_e - x) < T_o(\bar{u}_o - x) \tag{17a}$$

$$L_2^e(\bar{u}_e - x) > L_2^o(\bar{u}_o - x) \tag{17b}$$

If (17b) is fulfilled, it means that at any location with equal distance from the radius of town, more land is allocated for transportation in the town without congestion tolls (town e) than in the one with congestion tolls (town o). Less land will be allocated for dwelling at each such location in town e and therefore fewer residents will live there (than in town o). Equation (17a) is thus implied. If, on the other hand, we assume (17a), then between the town boundary and any given distance x from the boundary, fewer residents will live in town e than in town o. This implies that less land for dwelling and more land for transportation is allocated at this location in town e than in town o, which implies (17b). Hence, both relations in (17) must be fulfilled simultaneously. This implies that if both towns are of the same population size, town e must be more spread out than town o, i.e.,

$$\bar{u}_e > \bar{u}_o \tag{18}$$

The reason for this is that (17) implies that at any given distance x from $\bar{u}$, the density of population in town e is lower than in town o. For the two towns to be of the same size, ϵ must be further away from $\bar{u}_e$ than from $\bar{u}_o$ which implies (18).

The economic reasoning behind this argument is straightforward. Since land for transportation is a free product in the case without congestion tolls, it is abundantly used—so at every location there is too much land for transportation. Hence, the city is bigger than the optimal city size for the same population.

II. Average Total Cost

It is interesting to investigate the behavior of the total housing and transportation cost in this model as a function of population size. Mills and de Ferranti refer briefly to this question in the last section of their paper. They state that the average total cost for a low level of population size in the optimal town decreases when the population increases up to a certain minimum level of average total cost (ATC). A further increase in population size will cause ATC to increase. Hence, the city size in that minimum level of ATC is the optimum city size. This result has been questioned in the past,[1] since there is nothing in the model that permits economies of scale. It is proved in the following that ATC and marginal costs increase with population size at any level of population. It follows that no optimum city size exists.

Let us consider an optimal town with any given population N. We now reduce this population by an arbitrary quantity ΔN, $0<\Delta N<N$. The reduction will be done in a specific way and in two stages. The town at the final stage will be a feasible town, with total cost reduced more than proportionally to the reduction in population. It follows immediately that in an optimal town of the same population, the total cost will be even lower. Hence, marginal and average costs

---

[1] David Pines was the first to mention to me his doubts about this result. Mills himself also expressed, in a private communication, his doubts concerning this result.

increase monotonously at any given level of population.

Let us clarify the original optimal town with population of N by the subscript a. In the first stage, we reduce the population of town a by ΔN to get town b with a population $N-\Delta N$. The reduction is done by removing ΔN families living farthest from the center, and leaving the rest of the population intact. We then get a town with a new radius $\bar{u}_b$ and population $N-\Delta N$. Let us further reduce $L_2(u)$ at each $\epsilon<u<\bar{u}_b$ by the proportion $\Delta N/N$. The total cost of this new town, b, is less than a proportional reduction of the total cost of town a.

To prove it, let us consider the total cost function (5) and write it as follows:

$$TC = \int_{\epsilon}^{\bar{u}} p(u)T(u)du + SR_A \tag{19}$$

where S is the total area belonging to the town between ϵ and $\bar{u}$. The term $p(u)$ is given by (1), with $\bar{p}=0$.

First we prove that $S_b<S_a(1-\Delta N/N)$ where S_i — total area of town i and $S_i=L_1^i+L_2^i$ and where:

$$L_1^i = \int_{\epsilon}^{\bar{u}_i} L_1^i(u)du \tag{20a}$$

— total residential area in town i

$$L_2^i = \int_{\epsilon}^{\bar{u}_i} L_2^i(u)du \tag{20b}$$

— total land for transportation in town i

$i=a, b, c$, is an index of town

$$L_1^b = \left(1-\frac{\Delta N}{N}\right)L_1^a$$

since residential land is proportional to population.

$$L_2^b(U) = (1-\Delta N \mid N)L_2^a(u) \qquad \text{for } \epsilon < U < \bar{U}_b$$

Hence,

$$L_2^b < \left(1-\frac{\Delta N}{N}\right)L_2^a$$

since $L_2^a(u)$ was reduced proportionally for $\epsilon\leq u<\bar{u}_b$ and eliminated completely for $\bar{u}_b<u\leq\bar{u}_a$. It follows that

$$R_AS_b < \left(1-\frac{\Delta N}{N}\right)R_AS_a \tag{21}$$

From the definition of $T(u)$ in (4), it follows that

$$T_b(u) = T_a(u) - \Delta N$$

Putting $T_a(u)$ outside the brackets, we get

$$T_b(u) = T_a(u)\left(1-\frac{\Delta N}{T_a(u)}\right)$$

By substituting N for $T_a(u)$ in the denominator, we get, since $N\geq T_a(u)$

$$T_b(u) \leq T_a(u)\left(1-\frac{\Delta N}{N}\right). \tag{22}$$

and equality holds only when $T_a(u)$ equals N or zero.

From equation (1) with $\bar{p}=0$, we get

$$p_b(u) = \rho_1(T_b(u)/L_2^b(u))^{\rho_2}$$

Dividing the numerator and denominator by the factor $(1-\Delta N/N)$, and then substituting in the result $L_2^a(u)$ and $T_a(u)$, we get

$$\begin{aligned} p_b(u) &= \rho_1[(T_b(u)/(1-\Delta N/N) \\ &\qquad /(L_2^b(u)/(1-\Delta N/N))]^{\rho_2} \\ &\leq \rho_1(T_a(u)/L_2^a(u))^{\rho_2} \end{aligned}$$

hence,

$$p_b(u) \leq p_a(u)$$

From the above and (19), it follows:

$$T_b(u)p_b(u) \leq T_a(u)p_a(u)\left(1-\frac{\Delta N}{N}\right) \tag{23}$$

and equality holds only when $T_a(u)$ equals N or zero. Hence,

$$\int_{\epsilon}^{\bar{u}_b} p_b(u)T_b(u)du < \left(1-\frac{\Delta N}{N}\right)\int_{\epsilon}^{\bar{u}_a} p_a(u)T_a(u)du \tag{24}$$

By summing up (21) and (24) and substituting (19) into the result, we get

$$TC(b) < (1 - \Delta N/N)TC(a) \tag{25}$$

However, our proof is not yet complete, since town b does not fulfill all the requirements of a town in the model; at every $\epsilon < u < \bar{u}_b$ in b, there is a greater part not belonging to the town than the $(2\pi - \theta)$ allowed. We therefore change town b into town c by moving people from the town limits into the surplus vacant land inside the town. This transfer once again reduces TC by reducing $T(u)$ and $\bar{u}$, i.e., $T_c(u) < T_b(u)$ and $\bar{u}_c < \bar{u}_b$, while L_1 and $L_2(u)$ remain unchanged. Hence,

$$TC(c) < TC(b) < (1 - \Delta N/N)TC(a) \tag{26}$$

Town c fulfills the requirements of a town in the model. This completes the argument.

Externalities, Extortion, and Efficiency

By GEORGE DALY AND J. FRED GIERTZ*

A number of major contributions to welfare economics in the last decade or so have emphasized the important role that can be played by voluntary exchange arrangements in achieving efficient levels of externality generating activities (see Ronald Coase; Ralph Turvey). These contributions seem to have been widely interpreted by their authors and others as questioning the necessity and/or desirability of collective intervention in many environments characterized by external effects. For example, in a paper summarizing this literature, Turvey writes:

> The first [main conclusion of the literature] is that if the party imposing the external diseconomies and the party suffering them are able and willing to negotiate to their mutual advantage, state intervention is unnecessary to secure optimal resource allocation. [p. 309]

More recently, however, such conclusions have been called into question. Critics have noted that the reliance on private bargaining to control the creation of externally harmful activities may well have the adverse effect of encouraging the very phenomena it seeks to control (see Jerome Rothenberg; E. J. Mishan). The possibility of the promotion of extortionate transactions casts doubt on the viability of bargaining as a means for the internalizing of externalities (see also Donald Shoup). In response to assertions of this sort, Harold Demsetz has recently argued that extortion constitutes a problem only if competition does not exist in the supply of extortion services. He has further stated, pp. 445–46, that extortion is a legal not economic concept, i.e., from an economic standpoint, it differs little from other types of transactions. It is apparent, then, that general agreement has not been achieved regarding either the likelihood of extortion or its probable impact on the allocation and distribution of resources in environments characterized by harmful external effects. Among the important issues which remain unresolved are the following: Does there exist a fundamental distinction between externality generating activities that do yield private benefits and those that do not, as Rothenberg, Mishan, and others argue? Or is such a distinction irrelevant from the viewpoint of economic analysis, as Demsetz suggests? If extortion is a meaningful category, does the existence of competition in its provision significantly affect its impact on allocative and distributive activities? The purpose of this paper is to examine these and related questions concerning the nature and consequence of the bargaining process when external effects are present.

I. External Harm and Bargaining: Some Neglected Aspects

Traditional (i.e., Pigovian) discussions of external effects have implicitly assumed that negotiation or bargaining is not possible between the parties involved; that "independent" behavior will characterize those parties involved in an externality relationship.[1] This assumption of independent behavior means that individuals are concerned only with their own choice variables and are ignorant of and/or indifferent towards the impact that behavior will have on others and, hence, will have no incentive to undertake activities which exert external harm but fail to yield private benefits. Thus, the assumption of independence precludes the undertaking of "bribe-motivated" activities be-

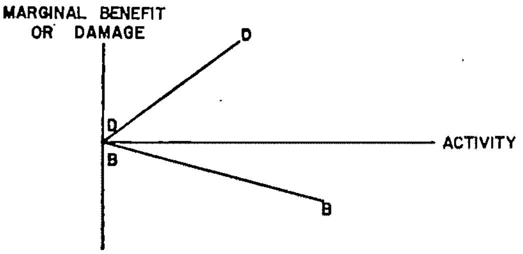

FIGURE 1

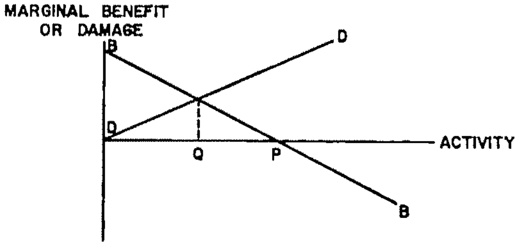

FIGURE 2

cause of the impediments to bargaining it implies.

It is this assumption of independent behavior which has been attacked in the more recent "Coase-inspired" literature. Yet this literature, while emphasizing the possibility of negotiations, has failed to note a vital fact: if bargaining *is* possible there is no a priori reason for ignoring the existence and consequences of externally harmful activities which fail to yield direct private benefits but can yield profitable side payments. That is, if bargaining is possible in cases where direct private benefits accrue it may also be possible where they do not. The economics of this latter case, ignored in the conventional literature, forms the main focus of this paper.

The term extortion refers in a general way to the act of obtaining payments from some entity in return for *not* imposing upon that entity some harmful effect, where the generator of the external effect receives no direct net internal benefit from the act. It is very important to distinguish between what we have labeled extortion and other bargaining situations where the externality generating party does receive direct net benefits.

Certain aspects of and contrasts between these cases can be clarified with the aid of some simple geometrical constructs. Consider a two-person world in which one of the individuals can engage in an activity which directly harms the other. Suppose that we measure the level of this activity on the horizontal axis and measure (in terms of some numeraire commodity) the evaluation that both individuals place upon this activity on the vertical. We abstract from income effects by assuming that for both individuals the marginal utility of the numeraire commodity is constant so that the individuals' marginal evaluation schedules can be used as demand curves.

In Figure 1, we measure the potential victim's marginal evaluation of the damage caused by the activity by schedule *DD* in the positive quadrant. Such a schedule shows the maximum amount this individual would pay to avoid the damage caused by an additional unit of the activity. The schedule *BB*, on the other hand, measures the direct marginal benefits net of cost to the individual whose activity imposes the external harm. It is in the negative quadrant indicating that the externality generating activity is costly and yields no direct benefits. With the possibility of bargaining (i.e., nonindependent behavior), such a situation clearly presents the potential for extortion with one person, the "victim," paying the other, the "extortionist," to refrain from an activity which yields the extortionist negative direct benefits. Successful negotiations, i.e., extortion, will lead to zero units of the activity produced and in absence of transactions costs would achieve Pareto optimality.[2]

Figure 2, on the other hand, illustrates the standard bargaining situation discussed in the externalities literature. In the absence of any impediments to bargaining, negotiations would lead to point *Q* where, as in Figure 1, joint benefits would be maximized and Pareto optimality would result. It is useful to note that in the context of Figure 2, bargaining has the potential for improving the allocation of resources as compared with the situation resulting from independent behavior. In contrast, extortionate bargaining (Figure 1) at best has the potential for duplicating the allocation of resources which would obtain under independent behavior.[3]

---

[2] Under these circumstances, i.e., absence of transactions costs, the act of extortion simply redistributes a consumer's and/or producer's surplus but does not affect the allocation of resources. It should be noted that for this condition to hold there must be no loss to the victim other than the resources he gives up to the extortionist. If, of course, the threat itself directly lowers the victim's utility (independently of the payment he must make), then the extortion is not costless.

II. Extortion and Allocative Efficiency

Extortion is clearly a pejorative term. It is important to analyze why this type of mutually agreeable exchange is held by society to be undesirable while other types of bargaining are relied upon in many circumstances to perform a socially useful task of producing a more efficient allocation of society's resources. While extortion redistributes wealth and is sometimes condemned on the basis of equity, there also seem to be important allocative reasons for its disfavor as well which relate to the costliness of the bargaining process.

Any bargaining process is a resource-using process.[4] Thus, in evaluating its effects on social welfare, the potential allocative gains resulting from that process must be weighed against the transactions costs generated. In each instance we must ask, "What are the allocative gains produced?" and "What are the costs incurred in producing them?" As Coase has pointed out, the Pigovian presumption that negotiations will not materialize in externality situations is tantamount to assuming that in each instance the relevant transactions cost will outweigh any potential allocative gains. It is also, as we have seen, to deny one of the necessary preconditions of extortion.

Consider these remarks in the context of Figures 1 and 2 above. As we have noted, the traditional Pigovian analysis has assumed "independent" behavior. This means that the individual will undertake each activity up to that point at which its net private benefits are zero. In Figure 1, independent behavior which implies the absence of bargaining would lead to zero units of the activity, while in Figure 2 it would result in P units. Thus, independent behavior produces inefficiency in the traditionally analyzed context of Figure 2 while, on the other hand, it produces efficiency in the case presented in Figure 1. In other words, *it is precisely the characteristic of independent behavior which produces nonoptimal allocation in the traditional externality relationship that produces optimality in situations where net private benefits do not exist.* Ironically, situations involving publicness and the attendant free-rider problems which often preclude the achievement of optimality through bargaining in traditional analyses may, in this situation, guarantee optimality by precluding effective negotiations and thus extortion.

Next, consider the social usefulness of the bargaining process in the two situations discussed above. As we have already noted, this process can lead to potential improvements in social welfare when the allocative gains it provides exceed the transactions costs it imposes. Those allocative gains, of course, are measured with reference to the allocation of resources in the absence of bargaining, that is, with independent behavior.

Viewed in this light, a fundamental distinction between the cases portrayed in Figures 1 and 2 emerges. Conventional bargaining (Figure 2) can lead to a superior resource allocation and therefore, depending upon the size of the transactions costs, may improve social welfare according to the Pareto criteria. On the other hand, the possibility of bargaining (i.e., extortion) in the context of Figure 1 can under the most favorable conditions (with zero transaction costs) only duplicate the results of independent behavior which produces allocative efficiency directly. With any positive level of bargaining costs, extortion will clearly lead to a reduction of social welfare since scarce resources are utilized in the process of negotiation while failing to improve the allocation of resources.

---

[3] The existence of extortion as defined above presupposes the satisfaction of several preconditions in addition to the existence of the potential extortionist and victim(s). The first, as we have noted, is that bargaining of some sort be possible between the parties involved. Secondly, it requires that the potential victim(s) enjoy a surplus from whatever activity the extortionist threatens. If such a surplus did not exist, the potential victim would be unwilling to pay the extortionist any positive sum for his services. Finally, given the existence of some extortable surplus and in a world of perfect foresight, the possibility of successful extortion also requires the existence of a technology and set of factor prices such that the costs to the extortionist of producing a credible threat are less than the "extortable" surplus. If this were not the case, extortion, although technically possible, would be unprofitable and thus in a world of rationality would not be undertaken.

[4] Several authors have noted that bargaining with respect to external effects is essentially a nonconstant sum game (see especially, Shoup). Since such games do not have determinant solutions, it is sometimes concluded that the associated transactions costs are infinite. Such a conclusion is clearly dubious and is not used in what follows. All that is assumed is that transactions costs are greater than zero.

It would appear then that there is a fundamental asymmetry between the social benefits of bargaining in the two cases, an asymmetry overlooked by economists' persistent tendency to exclude the case we have called extortion from their consideration. This tendency is particularly surprising since, as we have noted, situations involving external diseconomies and in which normal bargaining is possible are also likely to involve at some activity levels the possibility of extortion as well (for example, beyond point *P* in Figure 2). To the extent that this is so, the economists' case for negotiations in externality situations is of course correspondingly weakened.[5] Further, it is paradoxical that those authors who have stressed the possibility of negotiations have ignored extortion while, on the other hand, those who seem most skeptical of the possibility of negotiations in externality contexts have stressed its likelihood.

Finally, the above consideration suggests that in contrast to Demsetz's assertions, the distinction between extortion and other forms of bargaining has an economic as well as legal basis. Legal definitions of extortion seem to correspond rather closely to our Figure 1 situation (see Glen Mumey).[6] It would thus appear that the legal definition of extortion has a rather firm economic basis which in fact distinguishes it from other forms of bargaining. That is, the legal term extortion is applied to bargaining which can, like other forms of bargaining, redistribute wealth but which, unlike these forms, cannot improve the allocation of resources.

III. Extortion, Competition, and Efficiency

What effect will competition have upon the supply of extortion? Will it drive it out of existence as Demsetz (p. 445) seems to suggest? In more general terms, will it minimize the role played by extortion in the allocation and distribution of resources? Surely the issue is very complex and a thorough discussion of it would require an investigation of many complex, game theoretic consequences which might result from any negotiations. Nonetheless, several useful generalizations can be made.

First, as demonstrated in the preceding section, the effect of extortion on allocative efficiency depends upon the existence of transactions costs. With zero transactions costs, extortion or any other form of voluntary exchange simply redistributes wealth but does not use resources. In such a world all forms of voluntary bargaining are equally efficient. However, in a world of costly transactions, this is not so. Here extortion of the sort discussed in this paper uses resources and redistributes wealth but fails to improve allocative efficiency.

Of course, the simple fact that extortion involves costs does not necessarily imply that it is an undesirable method of allocating resources (see Gordon Tullock). As Coase has noted, all allocative methods involve costs. To accept or reject extortion on allocative grounds, we must know the nature of these alternative methods and, specifically, of their costliness. For example, extortion might well be the most efficient technique if the definition and enforcement of property rights to the amenities in question through the legal system and the prohibition of extortion were more costly than the process of extortion itself. On the other hand, if extortion could be prevented at zero cost, it would clearly be an inefficient means of allocating resources as noted above.

---

[5] This is not to argue, however, that collective intervention will necessarily improve things.

[6] Further, studies of actual cases seem to bear out such an assertion. For example, in a paper dealing with the question of conspiracy, R. A. Eastwood summarized the legal precedents as follows: "On this there has been much litigation, which I have not time to discuss in detail, but the results of the decisions, in my opinion, comes to this: that where the predominant or main purpose of the combination is not that of injury to others but the promotion of legitimate trade interests of those combining there is no tort, although others may incidentally suffer" (pp. 100–11).

What is clear, however, is that when extortion is a resource-using process the existence of competition in its supply is unlikely to either minimize its role or enhance allocative efficiency. Demsetz has argued that competition will drive to zero the price of extortionist services and, hence, that it will not be supplied. This confuses cause and effect. It is precisely the fact that extortionist services *are* supplied that drives the price to zero. Indeed, to argue as Demsetz has is to imply that a competitive industry in equilibrium will supply nothing since profits are zero. Moreover, if there are positive costs for the extortionist in establishing a credible threat, the price under competition will now approach these costs and not zero. In this circumstance the competitive provision of extortion services will clearly involve a net loss in social welfare by maximizing the resources devoted to this task. This would appear to lead to the worst of all possible worlds.[7]

IV. Conclusion

In a world of costless transacting, extortion (or any other form of bargaining) will not inhibit efficient resource allocation under either competitive or monopolistic circumstances; it may, however, result in profound changes in the distribution of income. When the process of extorting is a resource-using process, its existence will influence the allocation of resources as well as the distribution of income. Moreover, under these circumstances it is likely that competition will increase the use of resources and make extortion an extremely expensive method of allocating and distributing resources.

[7] In this context, it is instructive to note that organized crime's involvement in extortion often provides protection not just from their own imposition of the threatened action but from those of others as well. The elimination of competition in extortion does in fact provide a useful service in this case.

A Model of IQ, Occupation, and Earnings

By WILLIAM W. BROWN AND MORGAN O. REYNOLDS*

The objective of this paper is to present a simple model of causal relationships between three variables—IQ, occupation, and earnings. Relevant factors such as opportunity, risk attitudes, human investment, and motivation do not appear in the analysis, but the model produces implications which appear to be partially confirmed in preliminary evidence. Specifically, we present a model of the dependence of earnings upon IQ within and between occupations, show its implications for groups with different IQ distributions, and offer preliminary empirical tests with data from previously published studies.

I. The Model

Let income for the ith individual in the jth occupation be determined according to

$$Y_{ij} = a_j + b_j(IQ_i - t_j) + e_{ij} \tag{1}$$

where t_j is the required minimum or threshold IQ in occupation j; a_j is a parameter equal to average income when IQ is t_j in occupation j; b_j is a parameter>0; and e_{ij} is a random disturbance uncorrelated with IQ, with an expected value of zero, and a constant variance equal to $\sigma^2_{e_j}$.

Let a hierarchy of n occupations be defined by

(i) $t_1 < t_2 < \ldots < t_n$

(ii) $b_1 < b_2 < \ldots < b_n$

(iii) $a_1 < [a_1 + b_1(t_2 - t_1)] < a_2$
$< [a_2 + b_2(t_3 - t_2)] < a_3 < \ldots$
$< [a_{n-1} + b_{n-1}(t_n - t_{n-1})] < a_n$

That is, IQ thresholds and income coefficients increase with occupation. The last condition—that average income at threshold IQs exceed average income for those with identical IQs in the next lowest occupation—rules out intersections of average earnings functions for different occupations.

Now assume a normal distribution of IQ in the population and random assignment to occupations. That is, individuals are randomly drawn from the population and are randomly assigned to an occupation (all occupational assignments are equiprobable). If an individual's IQ is below the relevant threshold, he is not admitted to the occupation and is returned to the population for possible reassignment. If a randomly drawn individual's IQ is equal to or greater than the threshold of his randomly assigned occupation, he is employed in that occupation and his earnings are determined by (1). Under these conditions we have the following implications:

1. Average IQ in higher occupations will exceed average IQ in lower occupations.
2. Variation in IQ, measured by range or variance, will be greater in lower occupations.
3. Average earnings will be greater in higher occupations.
4. Implications 1 and 2 imply a negative correlation between mean IQ and IQ variation across occupations.

The first implication is simply an effect of truncation, where the conditional expectation of IQ monotonically increases with the value of the threshold t.[1] The second implication is obvious with respect to the range of IQs, but not for the other common measure of dispersion, variance. Following Arthur Goldberger we can show numerically

We wish to acknowledge the help of Dennis Aigner, John Conlisk, Arthur Goldberger, Eugene Smolensky, an anonymous referee, and the managing editor. They are not responsible for any errors remaining in the paper. An earlier version was presented at the meetings of the Western Economic Association, August 1973.

[1] A technical appendix, available upon request, illustrates implications 1–9.

that the variance in a truncated normal distribution declines monotonically with increasing truncation points up to +5.0 standard deviations beyond the original first moment.[2] Implication 3 is a statement about the conditional expectation of earnings and follows from the assumed earnings functions.

In addition to implications 1–4, one additional proposition may also be true, given that certain empirical magnitudes exceed others. Specifically,

5. Earnings variation will generally be greater in the higher occupation.

Proposition 5 can be demonstrated by stating the variance of earnings in the *j*th occupation as

$$\mathrm{Var}\,(Y_j) = b_j^2\,\mathrm{Var}\,(\mathrm{IQ}_j) + \sigma^2_{e_j}$$

If we assume that error variances are equal across occupations, proposition 5 requires that the steeper rewards (b_j) in higher occupations offset smaller IQ variances.

II. Implications for Groups with Different IQ Distributions

Consider two subpopulations, *A* and *B*, whose IQ distributions differ; specifically, normal distributions in which the mean IQ of *A* is less than that of *B* and the variance for *A* is equal to that for *B*. Given the random assignment mechanism and occupational hierarchy specified in Section I, we have the following implications:

6. If the population ratio of *A* to *B* is *r*, then the ratio of *A* in all occupations will be less than *r*. Also, the relative representation of *A* will progressively decline with higher occupations.

7. Assuming that all individuals with the same IQ earn equal incomes on the average (i.e., discrimination against either group does not reduce incomes), the average earnings of *A* will be less than *B* within all occupations.

8. Within an occupation *A* will have smaller variability measured by range or variance in both IQ and income.

9. Within an occupation the correlation between earnings and IQ will be less for *A* than for *B*.

10. Without controlling for occupation, the regression coefficient of earnings on IQ will be lower for *A* than for *B*.

Implication 6 is simply a property of the normal distribution in which the effects of group differences in the mean are magnified in the relative proportions in the tails of the respective distributions. All *A*s and *B*s are not employed because the IQ threshold for the lowest occupation necessarily excludes some people from employment. An IQ of, say, 65 may be required in the lowest occupation, which would exclude relatively larger numbers of *A* from the labor force.[3] That is, below this IQ *A*s exceed their population share and, by arithmetic necessity, above it *A*s are below their population share. Similarly, the higher an IQ threshold for an occupation, the lower will be the relative proportion of *A*s who are eligible. Implication 7 follows from the fact that within any occupation, the conditional expectation of IQ will be lower for *A* than for *B*. Implication 8 follows because for any truncation point a larger proportion of the *B* population is eligible.

We can demonstrate implication 9 as follows. In general, for a group *g* in occupation *j*, the correlation between income and IQ, $\rho(Y_{j,g}, \mathrm{IQ}_{j,g})$, is given by

$$b_j\sigma_{\mathrm{IQ}_{j,g}}/\sqrt{b_j^2\sigma^2_{\mathrm{IQ}_{j,g}} + \sigma_e^2}$$

Since $\sigma^2_{\mathrm{IQ}_{j,B}} > \sigma^2_{IQ_{j,A}}$, $(1+\sigma_e^2/b_j^2\sigma^2_{IQ_{j,B}})$ is less than $(1+\sigma_e^2/b_j^2\sigma_{IQ_j,A}^2)$. Rewriting the last two terms as fractions, taking reciprocals and square roots proves that the correlation for *B* will exceed that for *A*. Implication 10 follows because sampling from *A* and *B* would yield proportionately more *A*s in lower occupations where the effect of IQ upon earnings is relatively small, and regressing earnings on IQ yields lower IQ coefficients in the absence of controlling for occupation.[4]

---

[2] Goldberger shows the decline in conditional variances up to +2.0 standard deviations. Tables for the standard normal probability function allow further calculations to +5.0 standard deviations. The conditional variance for the standard normal distribution at +2.0 standard deviations is .11 and at +5.0 standard deviations it is .04. Conditional variances probably continue to decline beyond that point but we have been unable to prove it analytically.

[3] In addition, all *A*s and *B*s are not employed because the random assignment mechanism specified in the model is a sampling procedure, not one that operates until complete exhaustion of the population. This is a legitimate specification on its own terms but also note that subsequent data are samples rather than universes.

III. Some Evidence

Among implications 1 to 4, perhaps the most interesting is the prediction that mean IQ and IQ variation will be negatively correlated across occupations. One set of data, from Cyril Burt, consists of a large representative sample of adults in England. The occupational classification was based upon the "degree of ability required for the work," not upon prestige or income. The simple correlation between mean IQ and standard deviation across the six occupational classes is −.93. Another data set from Thomas Harrell and Margaret Harrell consists of the scores on the Army General Classification Test (*GCT*) for 18,782 white enlisted men in the Army Air Forces Air Service Command during World War II. The range of *GCT* is generally narrower in higher *GCT* occupations. For example, the highest occupation is accountant with a mean score of 128.1 and a range from 94 to 157 while the lowest occupation, teamster, has a mean of 87.7 and a range of 46 to 145. The correlation between mean score and standard deviation is −.89. World War II data from Naomi Stewart also confirm the fourth implication. The Army *GCT* scores for 81,553 white enlisted men are arrayed across 227 different occupations and the correlation between the median score and the semi-interquartile range across occupations is −.80. Leona Tyler (pp. 336–40) cites other data which confirm this prediction.[5]

Data from Phillips Cutright offer a source for preliminary testing of predictions about group differences in IQ and earnings. The sample consists of 25,000 white and 4,000 black men with Armed Forces Qualification Test (*AFQT*) scores during the Korean War. Subsequent Social Security data were matched to obtain earnings and educational attainment up to 1964. Table 1 presents some of the main features of these data. Because these data do not have occupational classifications, we can interpret education measured by years as a crude proxy for occupation.[6] Table 1 shows that the black mean *AFQT* and educational attainment are nearly one standard deviation below the respective white averages while the black earnings mean is about two-thirds of a standard deviation below that for whites. White standard deviations are substantially larger for *AFQT* and earnings, while the standard deviation for education is marginally higher for blacks. All correlations between variables are higher for whites than blacks, except those between earnings in different years. The correlation between *AFQT* and education is about 50 percent higher for whites than for blacks. The correlations between *AFQT* and earnings are

---

[4] While the model implies that the earnings-IQ slope will be higher for *B* than *A* independent of occupation (implication 10), whether the simple correlation between earnings and IQ will also be higher for *B* is an empirical question. Recall that the slope equals $\rho\sigma_Y/\sigma_X$, where σ_Y is the standard deviation of earnings and σ_X is the standard deviation of IQ. Alternatively, we can write $\rho=b\sigma_X/\sigma_Y$. The numerator is larger for *B* than for *A* but the denominator is also larger for *B*. Subsequent data show a substantially higher correlation between earnings and IQ for *B* (whites) than for *A* (blacks).

[5] The variance of IQ scores within occupations implies that correlations between individual occupational rank and IQ will be far from perfect. For example, these correlations are only .42 and .45 in the Harrell and Stewart samples, respectively. But because these samples were mostly for young men, the correlations are likely to be lower than in older civilian populations. The older a cohort is, the more likely it is that high IQ individuals have gravitated toward higher occupations and low IQ individuals toward (remain in) lower occupations. Data from the U.S. Employment Service (see Otis Duncan, David Featherman, and Beverly Duncan, pp. 98–101) for a civilian population has a correlation of .55 between intelligence and occupational status, about the same as the correlation between intelligence and scholastic achievement. Tyler, p. 343, also cites studies that IQs of school boys correlated .57 and .71 with their occupational status 14 and 19 years later, respectively.

[6] Educational attainment is generally correlated with occupation about 0.6.

TABLE 1

Variable	Mean	Standard deviation	Correlation Coefficients 1	2	3	4	5	6
Whites With 1962–64 Earnings ($N=24{,}819$)

about three times higher for whites (see fn. 4).

Table 2 presents a cross-classification of the Cutright data by education and *AFQT* score. The column totals illustrate the prevailing differences in *AFQT* distribution between whites and blacks. If we take the liberty of interpreting the five education rows as occupational groups, it is apparent that the relative representation is most different in the two extreme classes, with blacks three times more prominent in the lowest strata and whites four times more prominent in the top strata, as required by implication 6. Mean earnings generally increase with *AFQT* and education for both

TABLE 2—FREQUENCY DISTRIBUTION FOR MEN WITH 1962–64 EARNINGS, BY EDUCATION, *AFQT*, RACE, AND EARNINGS

groups as is generally expected, but within educational classes the average earnings of blacks are uniformly less than those of whites, which is consistent with implication 7. In addition, the association between *AFQT* and mean earnings is not as strong for blacks as for whites, which can easily be seen by inspection of Table 2.[7] The simple regression of 1964 earnings on *AFQT* yields a coefficient of $42 for whites and $18 for blacks, as predicted by implication 10. The coefficient is similar to the $25 obtained by W. Lee Hansen, Burton Weisbrod, and William Scanlon in a multiple regression of 1963 earnings upon *AFQT* and other variables for a national sample of 2400 low-achieving young men. Their sample was 47 percent white, 53 percent black, and had a mean *AFQT* of 9.1. Empirical work by John Hause (1971, 1972) is also broadly consistent with our simple IQ model. Hause uses four sets of data in regression analyses and argues that earnings coefficients for mental ability increase with education level, that is, IQ has very weak associations with earnings at lower educational levels. He also argues that IQ coefficients tend to become more important as labor force experience increases.

IV. Conclusion

The implications of our simple model require much greater testing against the Cutright data and other sources before preliminary acceptance is warranted, but the evidence does not contradict the model in any obvious way, despite its simple formulation. Some implications of the model might be interpreted as competing explanations for phenomena usually explained by various discrimination models. This is correct because the model helps to explain the occupational pattern for Chinese-Americans and Jews, as well as blacks, all of whom have been victims of discrimination but who occupy very different places in the occupational hierarchy. However, our model does not necessarily conflict with models which explain the labor market position of different ethnic groups by "discrimination." For instance, controlling for education and *AFQT* in the Cutright data eliminates less than half of the black-white earnings gap, which means that other differences exist between groups, perhaps discrimination and/or black disadvantages in other productivity characteristics.

To further illustrate that the labor market position of various groups cannot be entirely explained by IQ distributions, males and females have approximately equal IQ distributions but very different occupation-earnings distributions. Another example is that American Indians average about one-half of a standard deviation higher than the average for blacks on ability and achievement tests, but the occupational distribution is substantially lower for American Indians.[8] Nevertheless, a striking feature of the model is that substantial group differences in occupation and earnings occur if group differences in IQ distributions are coupled with a credible specification of the relationships between occupational earnings and IQ, even though a "discrimination-free" assignment mechanism is posited.

---

[7] Cutright does not report the correlations between *AFQT* and earnings within educational classes, which would permit a test of implication 9. But given that the correlations between *AFQT* and education, earnings and education, and earnings and *AFQT* are all substantially higher for whites than for blacks, it is improbable that the earnings—*AFQT* correlation within an educational class would be lower for whites.

[8] A related issue concerns the emerging evidence that there are stable ethnic and sex differences in patterns of mental ability (verbal, reasoning, number, space), which are invariant across wide socioeconomic classes (see Gerald Lesser, Gordon Fifer, and Donald Clark; Susan Stodolsky and Lesser; Tyler). The patterns of scores, in addition to a composite score like IQ, are bound to interact with occupational demands.

On Monopoly Welfare Losses: Comment

By R. CARSON*

In a recent article in this *Review*, Abram Bergson has challenged the thesis of Arnold Harberger, David Schwartzman, Michael Klass, Harvey Leibenstein, Dean Worcester, and others that the "welfare loss" from monopoly is apt to be inconsequential in a large economy, "such as that of the United States."[1] Instead, he argues that this loss may well be high, and that it "... is quite sensitive to empirical aspects which still seem unsettled ..." (p. 867). Bergson's contribution, which economists will applaud, is to measure the welfare loss within a general equilibrium framework. This is also the source of his challenge. Nevertheless, I shall argue that Bergson's conclusions stem largely from extreme assumptions about monopolistic pricing. When these assumptions are replaced by more "reasonable" ones, the small efficiency losses registered by previous writers are partially reconfirmed.

I. The Nature of the Monopoly Welfare Loss

Of course, firms in monopoly positions may do many things to cause welfare losses, broadly defined, and few economists would argue that the net impact of these together is necessarily small. However, in the conventional technical literature, the welfare loss from monopoly is solely an efficiency loss resulting from tendencies of imperfectly competitive firms (or cartel authorities) to set prices above marginal costs. Suppose that every good satisfies final consumer demands. Then the welfare loss from monopoly arises because the economy fails to produce the mix of goods and services that best satisfies consumer preferences. This is the loss measured by Harberger, Schwartzman, and Bergson. For a two-good economy, it is captured by Figure 1, basically a replica of Bergson's Figure 1. There the production-possibility frontier is assumed to be a straight line (analogous to constant long-run average costs), the community's preferences are described by indifference curves U_1 and U_2, and x_1 and x_2 index outputs in imperfectly and perfectly competitive sectors, respectively. Let P_1 and P_2 be the prices of these same goods.

If firms in both sectors set price equal to marginal cost, the economy will find its constrained bliss with the mix of goods denoted by A, and I_c will measure the community's income at competitive prices. On the other hand, if producers of x_1 set P_1 above MC_1

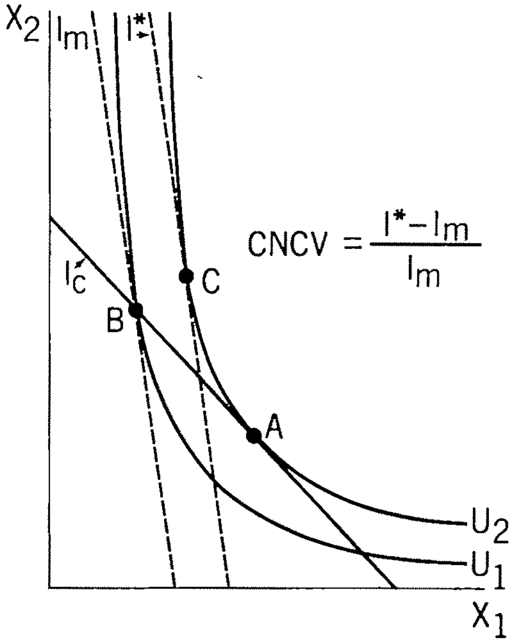

FIGURE 1

---

[1] See the references to Bergson, Harberger, Schwartzman, Worcester, Klass, and Leibenstein. Finally, see Frederic Scherer for an excellent summary discussion prior to Bergson. "Large" economy means specifically here that all industries and firms operate under constant costs.

while producers of x_2 set $P_2=MC_2$, the economy moves to the less-preferred combination at B. The income of the community at monopoly prices is given by I_m. If the level of welfare prevailing at A were to be restored at those prices, income would have to rise to I^*. As conventionally measured, the welfare loss from monopoly is the percentage difference between I^* and I_m or, in Bergson's terminology:

$$(1) \qquad CNCV = \frac{I^* - I_m}{I_m}$$

where $CNCV$ is the welfare loss in question.

The above is straightforward, but it requires an estimate of σ, the elasticity of substitution between the outputs of sectors one and two over segment AC of indifference curve U_2. Lacking this, empirical studies have used a partial equilibrium analysis instead, approximating the welfare loss as a loss in consumers' surplus, due to monopolistic pricing, not counterbalanced by increased profits in the imperfectly competitive sector. Bergson gives a lucid discussion of the error that may be built into such an approximation. I shall not repeat it here, but I show in the Appendix that for any *given* percentage markup of P_1 over MC_1 in the imperfectly competitive sector—or for any given production frontier and ratio of "with monopoly" prices—$CNCV$ is an increasing function of σ.[2] When all is said and done, this is the source of the high values of $CNCV$ that Bergson is able to generate.

II. Bergson's Model and Conclusions

One way to investigate the welfare loss from monopoly within a general equilibrium framework is to assume a community indifference map with the elasticity of substitution as a parameter, a particular production-possibility frontier, and particular price markups over marginal costs in monopoly sectors. Thus, Bergson supposes a linear production-possibility frontier, price markups that average 10 percent, 20 percent, and 30 percent, respectively, over MC, and an indifference map defined by the formula:

$$(2) \qquad U(x_1, x_2, \ldots, x_{n+1}) = \sum_{k=1}^{n+1} A_k x_k^{(1-1/\sigma)}; \qquad \text{for } \sigma \neq 1$$

Here, community welfare is some increasing function of U, the $\{A_k\}$ are constants, σ is the elasticity of substitution, assumed to be constant and the same between all pairs of goods, and the $\{x_k\}$ index production in different sectors of the economy. Perfect competition is assumed to hold in sector $(n+1)$ and imperfect competition elsewhere. Each firm is assumed to be vertically integrated from raw material supplies to final-use demand.[3] Let λ_k be the ratio of price to marginal cost in sector k and let γ_k be the percent of I_m (at monopoly prices) spent on x_k. Bergson also shows that:

$$(3) \qquad 1 + CNCV = \left(\sum_{k=1}^{n+1} \gamma_k \lambda_k^{\sigma-1}\right)^{1/\sigma-1} \left(\sum_{k=1}^{n+1} \frac{\gamma_k}{\lambda_k}\right)$$

for values of σ other than 1. He then proceeds to investigate $CNCV$ in two- and three-sector models, always assuming that the single competitive sector absorbs half of I_m.

In the two-sector case, Bergson calculated welfare losses (Table 1, p. 864) rise from .06 to 3.86 percent of I_m as σ increases from .5 to 64, with a monopoly price markup of 10 percent (i.e., $\lambda_1=1.1$). When $\lambda_1=1.2$, the welfare loss rises from .21 to 8.8 percent over the same range of σ, rising, say, from 1.66 to 3.20 as σ rises from 4 to 8. Finally with a monopoly markup of 30 percent, the welfare loss rises from .43 to 13.74 percent, reaching 1.73, 3.43, and 9.95 percent at σ values of 2, 4, and 16, respectively. To keep matters in perspective, it should be recalled that Harberger and

---

[2] Note that B in Figure 1 is the point where an indifference curve, whose slope is given by minus the ratio of the "with monopoly" prices, passes through the production frontier.

[3] If firms do not behave "as if" this were true, there may be additional welfare monopoly losses, due to price distortions in intermediate-goods industries, not captured in the discussion below. Klass has tried to measure these, using the *U.S.* 1958 input-output table. His results indicate that *at most* a 40 percent increase in welfare losses could have stemmed from this source.

Schwartzman calculated *CNCV* to be .1 percent of *GNP* or less, although a number of authors have claimed these to be underestimates.[4] In the two three-sector models considered by Bergson (Table 2, p. 865), *CNCV* is generally higher. For example, it can be as high as 11.54, 25.47, and 39.03 percent with $\sigma=64$ and price markups of 10, 20, and 39 percent, respectively, over marginal cost.

III. The Welfare Loss Recalculated

A problem with Bergson's approach is that firms are assumed to be completely oblivious to the elasticities of their demand curves. For any degree of competition in an imperfectly competitive industry, each firm will find that its demand elasticity rises with σ, a factor that would normally lead it to charge lower prices for higher values of σ. This could more than offset the above tendency for *CNCV* to rise with σ. Bergson is, in fact, often assuming that the ratios $(P-MC)/MC$, chosen by imperfectly competitive industries, will be many times those appropriate to profit-maximizing monopolies facing no threat of entry, government regulation, or countervailing power. In practice, the term monopoly must embrace a variety of forms of oligopoly, as well as the case where an industry is cartelized or consists of but a single firm. Even an absolute monopolist is likely to encounter government regulation or some other form of countervailing power that effectively limits its ability to mark up price above marginal cost.

In this context, let η be the elasticity of demand facing a particular industry, computed according to the formula:

$$\eta=\sigma-\gamma(\sigma-1) \tag{4}$$

where γ is again the percent of I_m absorbed by this industry. Let ϵ be the demand elasticity relevant to a particular price-setting decision maker within the industry. As a profit maximizer, he is usually assumed to try to set his price equal to:

$$\frac{\epsilon}{\epsilon-1}MC \tag{5}$$

which is a markup of $100/(\epsilon-1)$ percent over *MC*. Evidently, $\epsilon\geq\eta$, provided the monopoly does not reach beyond the "industry" defined above. Otherwise, we lack a specific link between ϵ and η unless we assume with Bergson that every identifiable product constitutes a separate good produced by a separate industry. Then $\epsilon=\eta$, but now the elasticity of substitution between the services of a Gremlin and a Pinto must be the same as that between the services of a Pinto and oranges.

At some cost of theoretical purity, we could instead take η to be the elasticity of demand for a product group and ϵ to be the (often higher) elasticity facing a "representative" producer within the group whose P/MC is average for the group as a whole. Bergson does not do this because he feels that such "horizontal aggregation" will conceal welfare losses. This conclusion follows from the higher losses recorded in his three-sector over his two-sector model, for given σ and average price markups in monopoly sectors (pp. 864–65). I shall return to this matter below.

Bergson also argues that (5) " . . . can be [no] more than very broadly applicable to real world monopolies . . . " (p. 861). This point is in fact crucial to his argument because accepting (5) as an upper bound to monopoly prices does not permit them to be raised indefinitely without regard for demand elasticity. Evidently, firms intending to maximize profits will sometimes err, setting prices too high or low on that account. But there is no reason for the expected value of these deviations to be anything other than zero. Moreover the standard error of this estimate in an economy with hundreds of thousands of decision makers setting prices and billions of goods to be priced is likely to be minuscule because of the law of large numbers.

In addition, there are at least six other reasons often mentioned in the literature why $MC=MR$ may fail to hold. The first of these is collusion, including price leadership, which for simplicity I assume to take the form of joint profit maximization over more than one product. However, this will not cause (5) to be violated (with $\epsilon \geq \eta$) if η is the elasticity of demand for a class of goods at least as broad as the extent of the collusion. This is again a question of whether horizontal aggregation across substitute products conceals welfare losses.

---

[4] See the discussion by Scherer.

The other reasons for $MC=MR$ to be violated are goals other than long-run profit maximization, the threat of entry by new competitors (or of government regulation), the durability of many goods, misleading advertising, and X-inefficiency. But Bergson's assumption that the economy operates along its production-possibility frontier rules out the last two, although the efficiency losses that they cause *may* be high in the real world. The remaining factors tend to depress P/MC, assuming that alternative management goals are more expansive than long-run profit maximization, for any given level of costs, as the thrust of the literature on the subject appears to suggest.[5]

In short, using (5) to define maximal price markups instead of assigning them arbitrarily as Bergson does should give us an outer bound for monopoly welfare losses, other than those stemming from X-inefficiency and misleading advertising—that is, as monopoly welfare losses are usually defined.[6] (This is subject to settling the problem of horizontal aggregation.) Refer to Tables 1–3. Table 1 describes a two-sector economy in which a competitive and a monopoly sector each absorb 50 percent of I_m. Tables 2 and 3 each describe three-sector economies in which the lone competitive sector continues to absorb 50 percent of I_m. In Table 2, each monopoly sector absorbs 25 percent of I_m. In Table 3, the first monopoly sector absorbs 33 percent and the second 17 percent of I_m. All of this is identical with Bergson's scenario. The formulas at the bottom of the tables, derived in the Appendix from formulas (3), (4), and (5) above, give $CNCV$ as a function of parameters m and p, which take on the values indicated.

TABLE 1—THE PERCENTAGE "WELFARE LOSS FROM MONOPOLY" ($CNCV$) IN A TWO-SECTOR ECONOMY[a]

σ	$m=1$	$m=2$	$m=3$
2	33.3	4.2	**1.6
4	13.0	**2.5	1.0
8	** 5.9	1.4	.6
16	2.8	.7	.3
32	1.4	.4	.2
64	.7	.2	.1

Note: σ = elasticity of substitution; η = elasticity of demand for monopoly sector; ϵ = elasticity of demand for "representative" product group within monopoly sector ($\epsilon = m\eta$).

[a] $$1+CNCV=\left[1-\frac{1}{m(\sigma+1)}\right]\cdot\left[\frac{1}{2}\left(1+\left(\frac{m(\sigma+1)}{m(\sigma+1)-2}\right)^{\sigma-1}\right)\right]^{1/\sigma-1}$$

The first column of each table assumes that monopoly prices do in fact equal $\eta/(\eta-1)$ times MC, and we note that these results reverse Bergson's in two critical respects. First, as σ rises, $CNCV$ *falls*. Second, as the number of sectors rises, $CNCV$ also falls. The importance of the latter lies in Bergson's claim that horizontal aggregation of products understates the the true monopoly loss. If anything, aggregation appears to *overstate* the true efficiency cost as a comparision of Table 1 with Tables 2 and 3 indicates (taking the first column in each case).

Because the evidence cited above does not indicate an exaggeration of "true" monopoly welfare losses due to horizontal aggregation, I shall consider each sector to be a product aggregate in the remaining columns of Tables 1, 2, and 3. That is, ϵ is the elasticity of demand facing a "representative" decision maker whose price-to-marginal-cost ratio for the good in question is average for the entire monopoly sector. Thus $\epsilon \geq \eta$ must hold and, having considered the case $\epsilon=\eta$, we now take ϵ to be a multiple of η. Thus, column 2 of Table 1 assumes $\epsilon=2\eta$, while column 3 assumes $\epsilon=3\eta$. In each case, $CNCV$ falls as σ rises, and, of course, $CNCV$ falls for given σ as ϵ becomes a larger multiple of

---

[5] For example, William Baumol's sales maximizers set $P=MC$ when constant costs prevail. See, as well, Armen Alchian and John Palmer.

[6] See William Comanor and Leibenstein for a discussion of welfare losses due to X-inefficiency. My own view is that they have greatly overstated these losses.

Table 2—The Percentage "Welfare Loss from Monopoly" (*CNCV*) in a Three-Sector Economy (with Equal Monopoly Weights)[a]

σ	$m, p=1$	$m=1; p=2$	$m=1; p=3$	$m, p=2$	$m=2; p=3$	$m, p=3$
2	19.0	12.6	12.7	2.8	2.1	1.1
4	6.7	4.9	4.9	1.4	**1.0	.6
8	2.9	**2.2	**2.2	.7	.5	.3
16	1.4	1.0	1.1	.3	.3	.2
32	.7	.5	.5	.2	.1	.1
64	.3	.2	.3	.1	.1	0

Note: σ = elasticity of substitution; η_k = elasticity of demand for monopoly sector $k(\eta_1=\eta_2=\eta)$; ϵ_k = elasticity of demand for "representative" product in monopoly sector $k(\epsilon_1=m\eta;\ \epsilon_2=p\eta)$.

[a] $$1+CNCV=\left[1-\left(\frac{m+p}{mp(3\sigma+1)}\right)\right]\left[\frac{1}{2}+\frac{1}{4}\left(\frac{m(3\sigma+1)}{m(3\sigma+1)-4}\right)^{\sigma-1}+\frac{1}{4}\left(\frac{p(3\sigma+1)}{p(3\sigma+1)-4}\right)^{\sigma-1}\right]^{1/\sigma-1}$$

η. Tables 2 and 3 take the same approach with $\epsilon_1=m\eta_1$ and $\epsilon_2=p\eta_2$. (In Table 2, $\eta_1=\eta_2=\eta$, because each monopoly sector has a weight (γ_k) of $\frac{1}{4}$. In Table 3 sector one has a weight of .33, while sector two has a weight of .17). Again, *CNCV* falls as σ rises, and the three-sector models have smaller monopoly welfare losses than the two-sector model in comparable situations. (As in Bergson's computations, increasing the dispersion of the sector weights raises *CNCV*.)

Because the low values of σ now yield high monopoly welfare losses, we must next ask how low σ can "reasonably" go within the context we are considering. For any given maximal markup of *P* over *MC* over all monopoly sectors, each column in each table gives us a value of η_k where k is the monopoly sector with the highest price markup. From (4), we can translate this into a lower bound for σ. If we insist on some variation in price markups between the two monopoly sectors in Table 2, we must add the constraint $m\neq p$. The same constraint is necessary in Table 3 if we insist on a variation in price markups of 25 percent or more between the

Table 3—The Percentage "Welfare Loss from Monopoly" (*CNCV*) in a Three-Sector Economy with Unequal Monopoly Weights[a]

σ	$m, p=1$	$m=1;$ $p=2$	$m=2;$ $p=1$	$m, p=2$	$m=1;$ $p=3$	$m=3;$ $p=1$	$m=3;$ $p=2$	$m=2;$ $p=3$	$m, p=3$
2	20.4	17.7	8.8	3.0	18.1	8.3	1.7	2.6	1.2
4	7.4	6.8	3.5	1.5	7.1	3.2	**.9	**1.4	.6
8	3.2	**3.1	**1.6	.8	**3.2	**1.5	.4	.7	.3
16	1.5	1.5	.8	.4	1.5	.7	.2	.3	.2
32	.7	.7	.4	.2	.8	.3	.1	.2	.1
64	.4	.4	.2	.1	.4	.2	.1	.1	0

Note: See note to Table 2.

[a] $$1+CNCV=\left[1-\frac{1}{(2.0303\sigma+1)m}-\frac{1}{(4.8824\sigma+1)p}\right]\left(\frac{1}{2}+.33\left(\frac{2.0303\sigma+1)m}{(2.0303\sigma+1)m-3.0303}\right)^{\sigma-1}+.17\left(\frac{p(.83\sigma+.17)}{p(.83\sigma+.17)-1}\right)^{\sigma-1}\right]^{1/\sigma-1}$$

two monopoly sectors, a variation that is necessary to approximate the degree of variability observed by Harberger.

I shall assume a maximal monopoly price markup of 20 percent, ($\epsilon_1 = 6$) clearly considered to be extreme (and rare) by Harberger and Schwartzman, authors of the most frequently cited empirical works on the subject of monopoly welfare losses. Let σ_{ji} be the lowest permissible value of σ in column j of Table 1. I have identified σ_{ji} by placing a ** in each column of the three-sector tables where $m \neq p$, as well as in the two-sector table.

As any developed economy in the real world produces billions of separately identifiable goods and services, covering at least several thousand product categories, I shall take the largest loss from the two three-sector models—that is, 3.2 percent—as the maximum estimate of the monopoly welfare loss.[7] This is considerably above the losses calculated by Harberger and Schwartzman, but considerably less than Bergson's maximum estimate and would fall further as more sectors are taken into account. Unfortunately, the calculating costs of considering anything like a realistic number of sectors are prohibitive.

APPENDIX

I shall now prove that *CNCV* is an increasing function of σ, for given monopoly price markups, and derive the formula for computing *CNCV* in Table 3. Using formula (3), define Y as follows:

$$Y^{\sigma-1} = \left[\frac{1 + CNCV}{\sum_k \left(\frac{\lambda_k}{\gamma_k}\right)}\right]^{\sigma-1} = \sum \gamma_k \lambda_k^{\sigma-1}$$

Assuming the $\{\lambda_k\}$ to be constant, and differentiating with respect to σ gives:

$$(\log Y)\, Y^{\sigma-1} = \sum_k \gamma_k (\log \lambda_k) \lambda_k^{\sigma-1}$$

whence:

$$\log Y = \frac{\sum_k \gamma_k (\log \lambda_k) \lambda_k^{\sigma-1}}{\sum_k \gamma_k \lambda_k^{\sigma-1}}$$

It will be sufficient to show that *log Y* increases with σ. We have:

$$\frac{d(\log Y)}{d\sigma} = \frac{\left(\sum_k \gamma_k \lambda_k^{\sigma-1}\right)\left(\sum_k \gamma_k (\log \lambda_k)^2 \lambda_k^{\sigma-1}\right)}{\left(\sum \gamma_k \lambda_k^{\sigma-1}\right)^2} - \frac{\left(\sum_k \gamma_k (\log \lambda_k) \lambda_k^{\sigma-1}\right)^2}{\left(\sum \gamma_k \lambda_k^{\sigma-1}\right)^2}.$$

But the numerator may be rewritten as:

$$\sum_{i>j} \gamma_i \gamma_j \lambda_i^{\sigma-1} \lambda_j^{\sigma-1} \left[(\log \lambda_i)^2 + (\log \lambda_j)^2 - 2 \log \lambda_i \log \lambda_j\right]$$

$$= \sum_{i>j} \gamma_i \gamma_j \lambda_i^{\sigma-1} \lambda_j^{\sigma-1} \left[(\log \lambda_i - \log \lambda_j)^2\right]$$

Given that at least one $\lambda_k > 1$, at least one $\lambda_k = 1$, and all $\lambda_k \geq 1$, the last sum above must be positive.

Turning to Table 3, we have, from formula (5):

$$\eta_1 = \frac{P_1}{MC_1} = \frac{\epsilon_1}{\epsilon_1 - 1} = \frac{m\eta_1}{m\eta_1 - 1}, \quad \text{since } \epsilon_1 = m\eta_1$$

$$\eta_2 = \frac{P_2}{MC_2} = \frac{\epsilon_2}{\epsilon_2 - 1} = \frac{p\eta_2}{p\eta_2 - 1}, \quad \text{since } \epsilon_2 = p\eta_2$$

By assumption, $\lambda_3 = 1$; $\gamma_1 = .33$; $\gamma_2 = .17$; $\gamma_3 = .5$. From (3) we have therefore:

$$1 + CNCV = \left[.5 + .33\left(\frac{m\eta_1 - 1}{m\eta_1}\right) + .17\left(\frac{p\eta_2 - 1}{p\eta_2}\right)\right].$$

---

[7] If there are additional intermediate goods producing sectors in our model economies whose own monopoly-price distortions alter costs of final-use goods producers and thereby raise total monopoly welfare losses by the same maximal percentage observed by Klass for the *U.S.* economy in 1958, the total maximal welfare loss rises to 4.5 percent (see fn. 2).

$$\left[\frac{1}{2}+.33\left(\frac{m\eta_1}{m\eta_1-1}\right)^{\sigma-1}+.17\left(\frac{p\eta_2}{p\eta_2-1}\right)^{\sigma-1}\right]^{1/\sigma-1}$$

$$=\left[1-\frac{.33}{m\eta_1}-\frac{.17}{p\eta_2}\right]\left[\frac{1}{2}+.33\left(\frac{m\eta_1}{m\eta_1-1}\right)^{\sigma-1}+.17\left(\frac{p\eta_2}{p\eta_2-1}\right)^{\sigma-1}\right]^{1/\sigma-1}$$

From formula (4):

$$\eta_1 = \sigma - .33(\sigma - 1) = .67\sigma + .33$$

$$\eta_2 = \sigma - .17(\sigma - 1) = .83\sigma + .17$$

Substituting these results into the above yields:

$$1+CNCV = \left[1-\frac{1}{(2.0303\sigma+1)m}-\frac{1}{(4.8824\sigma+1)p}\right]\cdot\left[\frac{1}{2}+.33\left(\frac{m(2.0303\sigma+1)}{m(2.0303\sigma+1)-3.0303}\right)^{\sigma-1}+.17\left(\frac{p(.83\sigma+.17)}{p(.83\sigma+.17)-1}\right)^{\sigma-1}\right]^{1/\sigma-1}$$

The formulas for the other tables are derived in identical fashion.

On Monopoly Welfare Losses: Comment

By DEAN A. WORCESTER, JR.*

The long-standing belief that monopoly seriously misallocates resources, hurting consumer interest, received tremendously strong professional impetus in the writing of E. H. Chamberlin and Joan Robinson in the early 1930's. But statistical estimates by Arnold Harberger, David Schwartzman, and the author (1973) find losses trivial. Statistical studies by David Kamerschen and Frederick Bell show rather large losses, as much as 6 percent of national income, but seem to have defects (see the author, 1969).

Estimates showing small welfare losses have not satisfied many active scholarly experts studying industrial organization such as F. M. Scherer and William Shepherd, even less the regulatory authorities, Congressmen, radical economists, and the influential press. Recently, Abram Bergson reviewed Harberger's methodology, advanced an alternative procedure which avoids some flaws he finds in Harberger's approach, and published tables which display purely hypothetical ranges of welfare loss resulting from various assumed conditions. Bergson strongly implies that actual welfare loss is not "inconsequential" (pp. 864–68). But his more refined approach shares a basic defect with the above-mentioned researchers. All neglect rational behavior and fail to explore the relationship between firm demand and industry demand and supply. Thus Bergson's hypothetical tables display welfare losses for some combinations that cannot exist, and others that can exist only if monopolists choose values that grossly reduce their net income, even to large negative values.

This paper starts from well-known relationships between a firm's demand elasticity and profit-maximizing price, reviews the standard relationship between a firm's demand curve and the elasticity of its industry demand and supply curves, and proceeds to evaluate Bergson's and Harberger's efforts on the basis of what is known of statistical elasticities and margins of monopoly price above competitive price. Values that appear in Bergson's and Harberger's work are used throughout to facilitate exposition.

I. Elasticity, Monopoly Markups, and Welfare Loss

Estimates of elasticity of demand, or the elasticity of substitution, are critical to estimates of welfare loss because only the difference between competitive and monopoly price is subject to statistical determination. Output distortions are inferred from estimates of monopoly markups taken in conjunction with demand elasticity. The lower the elasticity, the smaller the output distortion and the smaller the welfare loss for a given monopoly price markup. Even small markups produce large welfare losses if elasticity is high enough.

Most statistically computed elasticities are small, often below unity, as displayed in Table 1. The zero and negative marginal revenues implied by unit and lower elasticities if relevant to individual firms are inconsistent with rational behavior. Hence, Harberger has been critized for using elasticities as low as -1.0. One of Bergson's innovations is to calculate welfare losses for elasticities of substitution as high as 64, which, for the situations he considers, involves elasticities of demand as high as -32.5 (p. 866).

Monopolistic competition theory implies that welfare losses are more properly based on demand curves facing individual firms, the elasticities of which may be very much higher than the computed elasticities in

Table 1, all of which are for industries.

There are two basic models that relate a firm's demand curve to that of its industry or group: a collusive and an independent pricing model. The collusive model supposes that each firm immediately matches the price of any other firm in the group, perhaps that set by a price leader. This, apart from nonprice competition, makes each firm's demand elasticity identical to the industry elasticity. Where this model applies, industry elasticities such as those presented in Table 1 are identical to firm elasticities and therefore are appropriate to the calculation of welfare loss, justifying Harberger's choice of unitary elasticity as a first approximation.

The independent pricing model is often expressed by a formula of the type:

$$e_f = \frac{1}{S} E_D - \left(1 - \frac{1}{S}\right) E_S$$

where e_f is the firm's demand elasticity, S its share of the market, E_D the elasticity of demand for its industry, and E_S the elasticity of supply of the rival firms. The same relationships can be shown diagramatically as in Figure 1, where we assume three firms with the same marginal cost curves, an industry demand elasticity of -1.0 and supply elasticity of 2.0 at the competitive price and output.

Under these circumstances the firm's demand elasticity is -7.0, and the welfare loss appears to be that represented by the large shaded triangle related to the firm's demand and marginal cost curves, and not the much smaller blacked out one related to the industry demand and supply curves.

Nevertheless, the -1.0 industry demand elasticity and the smaller triangle is relevant to the measurement of welfare loss. The reason is that the change of output Q_mQ_a by the monopolistic firm is partially offset by an opposite change, the amount AB, by its rivals, making the net change in the quantity of the good only Q_MQ_C. This amount can be found by applying ***industry*** demand elasticity to the margin between the competitive and the monopoly price, P_mP_c.

Figure 1 is identical to the diagram associated with the "dominant firm" which I have shown elsewhere to be unstable (1957). Depending upon cost conditions, the dominant firm either sacrifices quantity to maintain price by yielding market share to rivals until the firm loses influence, or, alternatively, its cost advantage is so great as to lead toward single firm monopoly. In the latter (rarely (observed) case, industry elasticity obviously becomes relevant. In the former, welfare loss is progressively lessened. Each firm's elasticity rises, approaching as S approaches zero the infinitely high elasticity of firm demand under pure competition. It follows that welfare losses tend to diminish over time in the absence of innovation that creates new short-run monopolies.

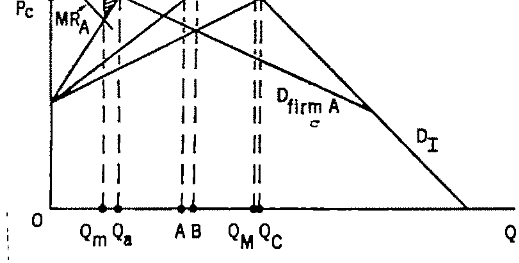

FIGURE 1. FIRM AND INDUSTRY ELASTICITY

The welfare loss calculated with industry elasticities appears to be the upper limit also in the short run. The still controversial sales maximization hypothesis would lead one to expect monopoly markups lower than the profit-maximizing ones where managers have the options that monopoly confers. Other motives such as the desire to run a larger enterprise, achieve financial advantages from size, hold market share in an expanding market, and perhaps price so as to discourage entry may also be served by lower margins. I also found maximizing strategy against uncertainty to involve lower margins (see the author 1967, especially p. 102). All of these require larger-than-monopoly outputs and smaller welfare losses.

I must conclude that not only are industry, not firm, elasticities relevant to the measurement of welfare losses, but also that industry elasticities overstate the size of loss.[1]

---

[1] Although industry elasticity is relevant for the calculation of welfare loss, elasticity by brand is of interest because it provides a basis for choice among alternative theories relating firm to industry demand. Keith Cowling recently calculated demand elasticities by brand for British cars, tractors, margarine, coffee, and toothpaste in order to isolate the effects of advertising. Quality differences were also estimated for cars. Quantity changes are given exclusively as market shares of industry sales. The elasticity of industry demand is not clearly stated (p. 101, n). The following tabulation presents Cowling's short-run demand elasticities (col. 1), and, where available, the industry elasticities for comparable *U.S.* industries. The brand elasticities are considerably larger and therefore inconsistent with the collusive price matching theory. Cowling declares his short-run estimates to be "much smaller" than the long-run ones (p. 101). For example, the long-run elasticity for British cars is given as -7.06. But there are statistical difficulties involving lags.

	(1)	(2)
Cars (*OLS*)	-1.950	-0.8 to 1.5 retail (H)
(*TSLS*)	-1.915	-0.6 short run (S)
Tractors mean	-3.290	—
1965	-4.630	—
Margarine (*OLS*) annual	-4.032	-0.3 (W)
Coffee (*TSLS*)	-0.202	—
Toothpaste (*OLS*)	-1.977	—

Sources: Cowling, p. 102; (H) Houthakker and Taylor; (S) Suits; (W) Weiss. The brand elasticities are, nevertheless, smaller than reasonably expected from the independent pricing theory.

II. What Values Can Properly Be Given to the Parameters?

The size of welfare loss depends importantly upon the size of the monopolistic sector, the extent to which monopolistic prices exceed competitive levels, the distribution of monopoly markups, and the size of the relevant elasticities. Definitive studies establishing these values do not exist, but it is possible to rule out wide ranges of values

The effect of the size of the monopolistic sector, however, is ambiguous on its face. As Joan Robinson pointed out long ago, a "world of monopolies" would produce exactly the same amount of each commodity as would a "world of competition," if each confronted the same (greater than unitary) demand elasticity. Only income distribution between marginal and residual claimants would be affected (ch. 27). I disputed even that (1967, pp. 199–208). But if monopoly power is said to exist only when a firm manages to hold its price consistently 5 percent or more above that needed to earn an average rate of return on investment, less than 6 percent of the firms covered by the *Fortune 500* survey qualified during the fourteen-year period ending with 1969 (see the author, 1973, p. 243).

The extent to which firms succeed in obtaining prices that produce high profits usually[2] affects the size of welfare loss, but to a lesser extent than might be expected. Data showing total net income as a percent of sales rarely suggest markups as high as 10 percent. A simple average of Harberger's industries has average monopoly price 1.072 of the average in the competitive sector. Suspicious investigators therefore look for profits hidden one way or another in costs. Rents, royalties, inflated executive emoluments, advertising, and inefficiency coincident with the choice of a quiet life are suspected hiding places. The alleged monopolist's margin over competitive price is then inflated on the implicit assumption that no function valuable to consumers is performed by these expenditures. But this view is weakening as writers such as Lee Benham and George Stigler (1961), to name only two, find advertising to be valuable to consumers as a source of information and a promoter of competitively lower prices; and as environmental economists rediscover the importance of rents to the allocation of resources, indeed to the very preservation of assets that yield rents.

Still, high margins can be generated. Kamerschen made a detailed effort to estimate the size of monopoly profits that may be hidden in categories not reported as profit for each of sixty industries. His data cover corporate and noncorporate sectors adding, in addition to reported profits in excess of average profits, all of advertising expense, royalties, and such intangibles as the return to patents, trademarks, and good will. He believes that he has also included rents. No allowance is made for profits hidden in executive compensation or wages, but neither was any effort made to exclude short-term profits that would appear in a fully competitive world during periods of adjustment to changed demand and supply conditions. Although Kamerschen recognizes as extreme the allocation of all of advertising to monopoly profit, he believes that on balance he underestimates the size of monopoly markups.

The size of his markups is not published, but its average size can be estimated by comparing the size of the welfare losses when he uses an elasticity of -1.0 to those when he uses a "Lerner" elasticity calculated from the standard equation for elasticity, $P/(P-MC)$, where in this case P is the monopoly price and MC is the competitive price calculated as P minus his estimate of monopoly profits per unit of output.

Kamerschen's choice from the thirty-two pairs of welfare losses displayed in his Table 1 (p. 230–31) shows a welfare loss of 6.11 percent of national income for the computed elasticity, and 1.87 for unit elasticity. Since the welfare loss at higher elasticities is the loss under unit elasticity times the higher elasticity, this yields an implied elasticity of -3.26, which, if $P_c = 1.0$, produces a monopoly markup of 44 percent of competitive price or 30.5 percent of actual price. It is difficult to reconcile this markup with national account data that show compensation of employees in the corporate sector claiming 66 percent of gross product originating in nonfinancial corporations.[3]

---

[2] An exception relates to decreasing cost industries that may earn high profits by price discrimination that markedly improves resource allocation. This is an aspect of the typical assumption that all industries operate at constant cost. Where rising cost is the fact, welfare loss is also overstated.

We leave the matter of size of monopoly markups unresolved, but with considerable skepticism attached to values which require net income above competitive levels to exceed 15 percent of sales for more than a few years.

More interesting is the fact that this high markup, taken in conjunction with the profit-maximizing assumption that makes it determine the elasticity of demand used to compute welfare loss, produces a loss of "only" 6.11 percent of national income. If the industry elasticities displayed in Table 1 were used in connection with Kamerschen's markups, as is appropriate, welfare loss would be considerably below the 1.87 percent of national income he gives for unit elasticity. This points up the importance of the third variable that affects the size of welfare loss, elasticity.

It is evident that the −3.26 elasticity computed from Kamerschen's high monopoly markup is much higher than those found in Table 1. Sixty-three of the ninety-six industries have elasticities less than unity, and the lower end of ranges given for five more fall below −1.0. These imply negative marginal revenue curves, and monopoly markups larger than the total price if each firm enjoys a market share demand curve. An additional twenty-five would have markups of 100 percent to 50 percent of price if their industries were monopolized: Some economists have argued that such data imply that the firms are not profit maximizers, and for various reasons produce more than the profit maximizing amount. An argument more in accord with economic analysis is that they are not monopolists.

Examination of the second theory relating firm demand elasticity to industry elasticities of demand and supply suggests why we should expect to find what is usually found, relatively small markups by profit-maximizing oligopolists despite very low industry elasticities. An oligopolistic firm's demand curve is much more elastic than its industry's if they do not collude. For example, apply the equation for independent pricing to the second largest *U.S.* oil company which has about 5 percent of industry sales. If the industry demand elasticity is a reported −0.46 and the elasticity of other firms' supply is assumed to be a very inelastic 0.25, the firm's demand elasticity comes to −13.95. Pricing to maximize profit with this demand elasticity suggests a margin about 7.7 percent above the competitive level. An attempt to establish a larger markup would insanely reduce profits. Smaller industry shares and larger supply responses by other firms drastically lower the margin. If the elasticity of supply is 1.0 instead of 0.25, the firm's demand elasticity is −28.2 and the profit maximizing markup over competitive price only 3.67 percent. The same figures for the largest *U.S.* oil company are approximately −13.6 and 7.9 percent. But the largest firm has no assurance that the others will not increase capacity and output more rapidly should it maintain the higher price for a period of time.

One may doubt the significance of such high coefficients. After all, firms are subject to the same general influences and tend to move their prices in the same direction at about the same times. Thus high elasticities are rarely if ever observed. But such argument misses the point. Competitive firms move their prices more or less together in response to commonly felt market influences. Statistical demand curves as a result are relevant to generic products, not the outputs of individual firms. High elasticities are relevant to independent behavior. Remorseless discipline constrains firms attempting to raise a price for reasons other than the general market influences felt by others.

---

[3] One puzzle is the size of the welfare loss, 1.57 percent of national income, found by Kamerschen when unadjusted profit data and unit elasticity are used. The assumptions would seem to accord with Harberger's assumptions and procedures which produced a welfare loss of only 0.08 percent. The most likely explanation of the difference involves Kamerschen's inclusion of the noncorporate sector which may substantially widen the range of return around the average. Still, the estimate seems high.

In principle, collusion offers benefits to each firm in an industry. But a firm with only 5 or 10 percent of the market can hope to gain by surreptitious price cuts not easily detected or policable by rivals.[4] Private oligopoly has no enforcement power comparable to legal prices backed by civil and criminal governmental sanctions. Even those are imperfectly enforceable.

According to the statistical record the vast majority of profitable large firms operate on relatively narrow margins, securing prices that return less than 5 percent on sales above that necessary to earn average profits. This implies firm demand elasticities larger than twenty despite inelastic or very modestly elastic industry demand curves, such as those calculated from statistical data. Armed with these tools and data we can analyze Harberger's and Bergson's studies of welfare loss.

III. Comparison of Harberger's and Bergson's Findings

Harberger applies a 1938 model developed by Harold Hotelling to Eptstein's data for seventy-three *U.S.* industries, 1924–28. Deviations from average profits divide the group approximately evenly into "monopolistic" and "competitive" sectors. The deviations of price from the competitive level are calculated from profit data, competitive prices being "too low" because on the relevant full employment assumption, overexpansion of the competitive sector follows reduced opportunities in the monopolistic sector where, of course, prices are "too high." Harberger assumes a universal unitary elasticity of demand to make possible a statistical estimate of welfare loss which turns out to be 0.08 percent of national income.

Bergson's approach is more elegant. He uses a constant elasticity of substitution (*CES*) utility function and a linear production function to calculate the compensating variation—the additional income consumers must receive to offset the loss of utility occasioned by monopoly pricing. The share of the total market monopolized, the size of monopoly price markup over competitive price, and different elasticities of substitution (used in place of demand elasticity), are built into his model. Potential welfare losses are found by assuming specific values for the parameters.

Bergson does not make estimates drawn from statistics. Instead, two tables are offered displaying welfare losses calculated for a number of hypothetical alternatives. In every case, half of the economy is competitive. Monopoly price is assumed to be alternatively 10, 20, and 30 percent above the competitive price. The elasticity of substitution is postulated, alternatively, as 0.5, 1.0, 2.0, 4.0, 8.0, 16.0, 32.0, and 64.0 (pp. 864–65). The relationship between elasticity of substitution and elasticity of demand given (p. 866) makes the equivalent demand elasticities the negative of 0.75, 1.0, 1.5, 2.5, 4.5, 8.5, 16.5, and 32.5 in this case. Welfare loss is highest where the monopoly markup is 30 percent and the demand elasticity is -32.5.

Since the object of Bergson's effort is clearly to provide theoretical support for the ancient belief that monopoly may seriously injure consumers, it is important to see if his model produces significantly higher estimates of welfare loss than others, such as Harberger's, when data gathered by others are plugged in. This is easy to do. Harberger's method also divides industry about 50 percent to monopoly, his deviations of returns on sales show average monopoly price to be 7.2 percent above the competitive price, and he assumes a unitary demand elasticity.

The natural comparison is to Bergson's result for monopoly prices 1.1 times the competitive level, calculated for a unitary elasticity of substitution equal to demand elasticity in this instance. The loss shown in Bergson's Table 1 (p. 864), 0.11 percent of national income, is about as inconsequential as the 0.08 percent found by Harberger for monopoly prices 1.072 times the competitive level.[5]

---

[4] For an acute analysis of this problem, see Stigler (1964).

[5] Nor is the effect of higher elasticities under Harberger-type analysis significantly different from Bergson's as long as monopoly prices are only 1.1 of competitive prices. The Hotelling analysis used by

Bergson finds a larger loss when the monopoly sector is divided into two parts, one with substantially higher prices than the other. Whether or not it becomes "consequential" depends partly on how big the loss must be to deserve that label, but it should be noted that the highest loss Bergson gives for unitary elasticity, the elasticity used by Harberger, is 1.29 percent of national income. That figure is based on the assumption that 17 percent of consumer expenditures are for products with prices 60 percent above the competitive level and 33 percent for products priced 15 percent above the competitive level (p. 865, Table 2, col. 6).

As can be observed from Bergson's tables (pp. 864–65), there are no truly large welfare losses in the absence of large elasticities. Only large markups in conjunction with extremely high elasticities of substitution, as high as 64, equivalent to -32.5 demand elasticity, produce values for monopoly loss that are certainly "consequential"—as high as 39.03 percent of national income. His practical conclusions therefore, rest most heavily upon the size of elasticities in actual markets.

Table 1 presents all the statistical elasticities of industry demands that a determined search of the available materials turned up. As may be seen, elasticity is above 2 in only eight instances, none in industries that absorb a large proportion of consumer income. Virtually every important industry has a demand elasticity less than -1.5, far less than the level required for consequential welfare losses in Bergson's tables even for monopoly markups as extreme as 30 percent for half of *U.S.* output, if welfare losses must exceed 2 percent of national income to be deemed consequential.

A much more serious objection must be raised against Bergson's tables. Most of the combinations of monopoly markup and elasticity are entirely ***inconsistent with profit-maximizing behavior***, and would indeed require firms to raise prices far ***above*** the profit-maximizing levels. When these combinations of elasticity and monopoly prices are omitted from Bergson's tables, maximum welfare losses ranged between approximately 2 and 4 percent.[6]

Even worse, the implied competitive equilibria calculated from combinations of markup and elasticities that produce high losses require large ***negative*** outputs in the competitive sector. This can be demonstrated with a simple constant cost numerical example. Let full employment income equal \$2.6, half spent at a competitive price of \$1, and half at a monopoly price of \$1.3. Total factor earnings are \$2.3; monopoly profits are \$0.3. Let price in the monopoly sector be cut to \$1, a reduction of 23 percent. We are at liberty to pick from Bergson's tables the equivalent of an elasticity of demand as high as -32.5. Suppose it is -30. The result is a 690 percent

---

Harberger allows one to calculate the effect of larger elasticities of demand by multiplying the welfare loss when elasticity is -1.0 by alternative demand elasticities (Harberger, note 2, pp. 81–82). Bergson's highest estimates are for an elasticity of substitution of 64. The demand elasticity equivalent is -32.5. Multiplying the 0.11 percent welfare loss when the demand elasticity is -1.0 by 32.5, we have 3.575 percent of national income. Bergson's method yields 3.86. Bergson's values diverge substantially from Harberger's when monopoly prices are 1.2 and 1.3 times the competitive level, but not in the direction favorable to Bergson's conclusion. He finds losses of 8.80 and 13.74 percent of national income when the elasticity of substitution is 64 (as compared to .41 and .86 when it is 1.0). The Hotelling-Harberger approach yields much larger values, 13.32 and 27.9 percent, respectively.

[6] These maxima require the assumption, seemingly popular in some quarters, that monopolists are malevolent, out to maximize harm to consumers regardless of cost to themselves. Monopolists can accomplish this either by raising their prices until the consumers can afford none of the monopolist's products, or by lowering price until the competitive sector is eliminated. The monopolist can price himself out of the market with price increases of either 20, 10, 5, or 2.5 percent as the demand elasticity is alternatively 5, 10, 20, or 40 ($\Delta Q/Q = -100$; $\Delta P/P = 100/E$). A reduction of sales of the initially competitive sector to zero involves lowering price enough to double total dollar sales, leaving nothing for the competitive sector. Reductions of .1, .2, and .3 used in Bergson's examples are percentage reduction of 9, 16⅔, and 23 percent. Since in each case the limits of production possibility are reached when monopoly output is doubled if true marginal costs equals competitive price 1.0, elasticity can be found by dividing the percentage change of price into the required 100 percent change of output. The elasticities are -4.35 when the monopolist's price reduction is from 1.3, -6.0 when it is from 1.2, and -11 when it is from 1.1. Note that the larger monopoly margins are associated with the smaller elasticities.

increase in output in the monopolized sector, to an output of 6.9. Under constant costs this requires a transfer of resources valued at \$5.9 to the formerly monopolized sector. This is \$4.6 more than the total employed in the original competitive sector. Thus, elimination of monopoly implies an impossibility, a large negative output in the original competitive sector.

Actually, the profit-maximizing markup when elasticity of demand is -30.0 is only 3.45 percent.

IV. Conclusions

Welfare loss literature suffers from the failure to apply standard propositions from the theory of the firm to the relationships between elasticity, marginal revenue, and profit-maximizing prices, and neglect of the relationship between the elasticity of a firm's demand curve and the elasticities of supply and demand of the industry of which it is a part. Bringing them in provides a rational explanation for the paradox of modest markups by profit-maximizing oligopolists in industries with inelastic demands. Standard theory also leads to the conclusion that it is correct to use industry elasticity of demand (not the firm's) to calculate welfare losses. When translated into the appropriate elasticities of substitution and applied to profit-maximizing markups on sales in the corporate sector, Bergson's procedure, more elegant than Harberger's, yields essentially his result. Nothing in Bergson's article provides any basis to believe in the relevance of markups or elasticities larger than those found by previous researchers. Examination of Bergson's case, therefore, does not controvert, but rather reinforces the hypothesis that monopoly losses are "inconsiderable."

It should be added that estimates of moopoly loss in labor markets by Bell and Albert Rees, not referred to by Bergson, find welfare losses somewhat larger than in consumer markets but still "small" especially, in the case of Bell, when welfare loss is confined to net changes from reallocation.

No doubt some true misallocation occurs in factor markets, thus shrinking the production possibility curve. The extent to which the value of the misallocated resources surface in profits and can be separated from functionally useful profits has not as yet been determined.

The time is surely close at hand for economists to accept the research findings that welfare losses due to enterprise monopoly are small in the American economy. On the evidence, industry approximates the competitive model, ancient and conventional wisdom, playwrights, publicists, John Kenneth Gailbraith, and many lucky business leaders to the contrary notwithstanding. The appearance of discretionary power is not the same as power. Business leaders, like all competitors, may typically occupy the position of the Red Queen, who had to run as hard and intelligently as she could to stay more or less in place, although apparently a royal despot and red at that.

On Monopoly Welfare Losses: Reply

By Abram Bergson*

I

In his very interesting note, Richard Carson undertakes to adapt the illustrative calculations on monopoly welfare losses in my 1973 article, so as to allow for certain relations among the underlying parameters. The relations in question, he believes, are indicated by the classical theoretic condition for monopoly pricing.

$$p/MC = \epsilon/(\epsilon - 1) \tag{1}$$

My illustrative calculations were intended to be just that, and from my own discussion of (1), pp. 861, 867, the reader, I think, will not be very surprised if losses are reduced when account is taken of that condition. Whether they must be as limited as Carson argues, however, is another matter. In any event, I do have misgivings about his computations, and hence also about his resultant "maximum estimate."

In making our calculations, both Carson and I apply a formula for monopoly welfare losses (my (18), Carson's (3)) that I derived on the assumption that in the economy considered there is but a single consuming household, though one that acts as a perfect competitor. Also, the household's indifference map is given by a *CES* function. As it turns out, losses then depend on the elasticity of substitution (σ) in that function, and on the magnitudes, for all products, of two further variables: λ_i, the ratio for the ith good of price to marginal cost, and γ_i, the share of expenditures on that good in the household's income. Note also that η_i the own-price elasticity of demand for the ith good, varies with σ and γ_i in conformity with a further formula that I derived: my (22), Carson's (4). Hence, for any given σ and any given magnitudes of γ_i for different products, there is a corresponding set of magnitudes of η_i.

While we thus take the same formula as a point of departure, Carson and I diverge in applying it. As implied, the divergence turns on the use made of (1). Thus, for purposes of my illustrative calculations, I in effect treated σ, λ_i, and γ_i as independent parameters, and allowed each in turn to vary over what seemed an appropriate range without regard to any constraint that might be imposed by (1). By implication, despite (1), I also allowed η_i and λ_i to vary independently.

Carson too takes σ as a parameter, and also allows γ_i to vary much as I did. As for λ_i however, that is given throughout by (1), on the understanding that ϵ is the "... demand elasticity relevant to a particular price-setting decision maker within the industry" (Carson, p. 1010). Also, several alternative hypothetical relations are entertained between ϵ and η_i the demand elasticity that is immediately relevant to monopoly welfare losses in my (22) (Carson's (4)): in an economy with two sectors, one of which is monopolistic, ϵ is taken in turn to equal η_i; 2 η_i, and 3 η_i.[1] In an economy with three sectors, two being monopolistic, each of the foregoing three relationships obtains in turn in each monopolistic sector, though the same relationship need not obtain simultaneously in both of them. What is to be said for this procedure as an alternative to mine?

In trying to answer, it should be observed first that the model that both Carson and I use is not entirely satisfactory for purposes of formally integrating (1) into the calculations. At least, what one might wish to allow for in that case is any resultant cross-sectoral covariation of η_i and λ_i over the relevant range. Given a *CES* indifference map, however, σ is necessarily uniform for all pairs of commodities. While η_i may still vary between commodities, the variation according to my (22) (Carson's (4)) necessarily is limited and awkwardly can occur only in dependence on the variation in γ_i. The latter, to repeat, is the share of the ith good in the household's budget.

---

* Professor of economics, Harvard University.

[1] Here and elsewhere, I follow Carson notationally in understanding that in relations such as are in question, ϵ like η_i pertains to the ith product; that is, ϵ pertains to the ith product, so far as (1) applies to that product. On whether the formula does so apply, see below.

While making illustrative calculations for a *CES* indifference map, however, I also developed formulas for monopoly welfare losses—(1), (5), and (8)—that apply more generally. Although relatively complex, these fairly clearly indicate that the losses must depend on, among other things, η_i and λ_i. Also, other things equal, the losses as might be expected must be greater the larger the η_i for a given λ_i and the larger λ_i for a given η_i. It was in the context of this more general model that I ventured to speculate (as I suggested above that I did) as to the possible import of (1) for monopoly welfare losses. We may also, I think, properly construe Carson in the same light. While losses are calculated within the framework of the *CES* model, the concern evidently is somehow to represent the impact of cross-sectional relations between η_i and λ_i such as might be indicated by (1).

Though evident, it is advisable to underline that η_i, the own-price elasticity of demand for a product, is understood in the usual way in terms of a demand schedule such as:

$$(2)\quad x_i = d^i(p_1, p_2, \ldots, p_i, \ldots, p_n, I)$$

The own-price elasticity of demand for x_i, then, is the negative of $(p_i/x_i)(\delta x_i/\delta p_i)$, where in the partial derivative all p other than p_i are constant; and so too, of course, is I, the household's income. Also, a product is understood as an item sold by a firm for which the ratio of price to marginal cost differs from the corresponding ratios for other items sold by either the same firm or other firms. Hence, as I state in my original article:

> . . . what counts is variation [in the ratio of price to marginal cost] not only between industries in any conventional sense, but between products; even between different qualities or models of the same product (for example, different models of Buicks) so far as price-cost ratios vary here as well. [p. 860]

These interpretations of η_i and of the concept of a product obtain as these aspects relate to the calculation of monopoly welfare losses under the *CES* model. They also obtain, however, where reference is to losses more generally.

To come back to Carson, evidently one question at issue concerns the principles of monopoly price formation. That is also a matter that is hardly to be settled here, but in applying (1), Carson, to repeat, takes ϵ to be the "demand elasticity relevant to a particular price-setting decision maker within the industry." On that understanding, I don't think there is any need to quarrel especially with his view of monopoly price formation in order to conclude that in his calculations he allows for some, but by no means all, cases of monopoly price formation that are of interest. In order to see that that is so, it suffices to recall pertinent theoretic precepts for the three main textbook sorts of monopolistic markets:

(i) *Monopolistic Competition*; i.e., where an "industry" consists of many small firms each producing a good similar to, but yet differentiated from, those produced by other firms, and where each firm fixes its price quite without regard to any impact its actions might have on its competitors. Here (1) must indeed hold in equilibrium, or so at least the primers teach us. In practice, there are the usual caveats as to business motivation and knowledge of costs and demand, but Carson claims no more for (1) than that there be a tendency for it to hold and I think we must grant a presumption to that effect. It also follows that λ_i should be more or less in conformity with (1), and that ϵ should approximate η_i. In short, here Carson's premises must be granted, at least if the primers are at all trustworthy. Indeed, the first of his three hypothetical relations between ϵ and η_i, that where the two elasticities are equal, is essentially the one that obtains.

(ii) *Pure Monopoly*; i.e., a single firm produces all of a product for which there are no close substitutes, and without there being any threat to speak of from potential rivals. The indicated conclusions regarding (1), λ_i, ϵ, and η_i are, of course, as in (i), so here too Carson is essentially validated, and with ϵ for the product in question equal to the corresponding η_i.

(iii) *Oligopoly*; i.e., the industry consists of relatively few firms producing more or less similar though not necessarily identical products. Here unfortunately, the primers, and indeed even the advanced texts, are not always as instructive as one might wish. But η_i for the product of any one firm manifestly might frequently be very large. In fact, depending on how similar the products of different firms are, η_i might even approach infinity. On the other hand, oligopolistic firms seem characteristically to avoid any very consequential price competition. Hence, in fixing the price of its own product, the individual firm is more or less concerned with the response of demand not only to a change in that price but to possible concomitant changes in the prices of similar products of his competitors. To what extent in such circumstances λ_i might still be explained by a simple formula such as (1) is an interesting question, but so far as it is the relevant ϵ clearly must often be less than η_i and possibly far less. In any event, λ_i should often be greater, and sometimes much greater, than (1) would indicate with ϵ taken to equal η_i.

At this point, then, Carson is surely wide of the mark. Thus, for oligopoly, one wonders whether there can be any systematic relation to speak of between λ_i and η_i. So far as there is, it evidently can hardly be such as Carson obtains when in applying (1) he improperly allows ϵ to equal η_i. The incongruity between his λ_i and η_i necessarily only becomes the greater in his alternative cases where ϵ is taken to equal 2 η_i and $3\eta_i$.

Why then does Carson delineate the domain of his parameters in that way? Apparently, his rationale is found in calculations indicating that, contrary to a finding of mine, disaggregation reduces calculated losses. Hence, in order to obtain an upper limit for losses, we may safely think of η_i as referring to a composite for broad sectors, rather than as I have urged is necessary, for finely differentiated products. By the same token, ϵ may be taken as being, if anything greater, rather than (as I have argued) less, than η_i. Or so Carson appears to reason, but I don't think properly.

We must distinguish two approaches to aggregation. In both, reference is to composites—to be precise, let us say Hicksian composites—for groups of distinguishable but related products. Under one approach, however, the price of each composite itself is supposedly set by a single hypothetical monopolist. Hence, the price-cost ratio for the composite conforms to (1), with ϵ taken as the elasticity of demand for the composite, or some multiple of that elasticity deemed typical for the market in question. Under the other approach, the price-cost ratio for the composite is simply taken to be the average of the price-cost ratios for individual products comprising it. Whichever the approach, the question is posed as to how calculated monopoly welfare losses are affected if in the computation, rather than consider the price-cost ratios for individual products in each composite, we allow the price-cost ratio for the composite to stand for all of them together. The answer to that question, however, evidently could differ depending on which of the two sorts of price-cost ratios for composites is referred to.

Of the two approaches, the second seems essentially the one applied in empirical research such as that in the pioneer paper of Arnold Harberger. Thus, Harberger focuses there on price-cost ratios that are in effect sectoral averages and have no relation to the single ϵ, unity, which is assumed to prevail everywhere. On the other hand, David Kamerschen in one of several computations does assume that (1) applies at a sectoral level. Curiously, however, that formula is used to estimate elasticities rather than price-cost ratios. The latter here, too, are in effect sectoral averages.

The difference between Carson and me regarding aggregation must be seen in the foregoing light. Of the two approaches, Carson clearly is concerned with that where a single hypothetical monopolist fixes the price of each composite. That approach, at any rate, underlies his computations; his exposition might sometimes suggest that he is proceeding otherwise. Carson's approach is of interest, but the results have no bearing one way or other on my finding that with disaggregation calculated losses increase, for I focus on the alternative approach where the price-cost ratio for each composite is simply an average of the price-cost ratios of the corresponding individual products. In applying that approach, moreover, I properly allow for divergencies in such price-cost ratios within any composite. In contrast, as we may infer, of six cases of disaggregation that Carson considers as vindicating his thesis, (i.e., two cases for each of the hypothetical relations allowed between ϵ and η_i), three are such that λ_i is the same for two subsectors in question. In all six cases, the λ_i for both subsectors are less than the price-cost ratio for their composite. I come in a moment to the reasons why Carson's price-cost ratios turn out to be restricted in these ways. Suffice it to observe now that with the ratios so restricted, none of Carson's six cases comes within the ambit of the kind of disaggregation on which I focused.

II

But granting the difference in approach, does it not remain true that for Carson disaggregation reduces calculated losses? If so, is he not warranted in thinking that, for purposes of deriving an upper limit for losses, my (18) (his (3)) may properly be construed as relating to composites; and hence that his calculations, when construed similarly, are illustrative of losses under monopoly generally, including oligopoly, even though he takes $\epsilon \geq \eta_i$? In a word, does he not by using his approach arrive after all at an upper limit for losses, as he seeks to do?

That seems more than doubtful when we consider further the six cases which Carson takes as demonstrating that losses decrease with disaggregation. As indicated, in all these cases sector and subsector price-cost ratios are related in rather special ways. There are two reasons for that. One is simply that Carson follows me in using a *CES* indifference map. Given that, the resultant need to conform to my (22) (Carson's (4)), and also Carson's imposition of (1)—given all that, as readily seen, Carson's sector and subsector price-cost ratios had to be rather special. Possibly for consumer's tastes more generally, disaggregation of the Carson kind would reduce losses but if so, that fact has still to be demonstrated.

The other reason why Carson's sector and subsector price-cost ratios turn out to be of very restricted sorts is that in disaggregating Carson focuses exclusively on "comparable situations." That means that ϵ in (1) is the same multiple of η_i in the two subsectors considered, and that for the corresponding sector it is also that multiple of the sectoral demand elasticity. Those restrictions probably pose no special difficulty where reference is to monopolistic competition and pure monopoly. In such markets equation (1) tends to obtain with ϵ generally approaching η_i for different products. On the other hand, under oligopoly as we saw so far as (1) applies at all, ϵ tends to vary in relation to η_i within a product group, and often markedly. To the extent that ϵ does so vary, therefore, the reduction of losses with Carson's kind of disaggregation remains unproven under oligopoly even with a *CES* indifference map.

Actually, the demonstration of that result can not be considered as extending to oligopoly in any event since cases where $\epsilon < \eta_i$ for individual products are illegitimately excluded even for the purposes of that exercise. But at this point it must be acknowledged that Carson himself is needlessly restrictive. While oligopoly must often entail $\epsilon < \eta_i$, as is easy to see, even with that relation disaggregation such as is in question still would reduce losses; provided, that is, that reference is still to a *CES* indifference map and to "comparable situations."[3]

I have been tacitly assuming that Carson's

---

[3] Although Carson refers only to cases where $\epsilon \geq \eta_i$ for subsectors, we may be able to gain some insight into the import of the varying relation of ϵ to η_i for individual products under oligopoly by juxtaposing some of Carson's calculations for situations that are not "comparable." Of particular interest I think are these cases: in Carson's notation $m=2$ for a single monopoly sector, and $m=1$ and $m=3$ for two subsectors. The sectoral multiple is thus the mean of the two subsectoral multiples, which seems appropriate under Carson's approach to aggregation. As seen from Carson's tables, disaggregation here markedly increases losses.

composites refer to product groups of a more or less conventional sort. That appears to be his supposition too. But what if attention were focused instead on very large segments of the economy, or even on one segment embracing each and every monopolized product produced? Might not the losses inflicted by the corresponding hypothetical monopolists be an upper limit for actual losses, at least in these cases? In fact, is that not quite possible whatever the nature of the indifference map and whether situations are comparable or not? No doubt it is, but the upper limit could be high indeed. To be aware of that, one need only ponder for a moment the possible impact of a single monopolist controlling, say, a country's entire food supply.

Whatever the scope of the composites, note that with Carson's approach to aggregation, pertinent price-cost ratios are necessarily those that hypothetical monopolists would fix for those composites. That needs underlining, for in trying finally to delimit monopoly welfare losses Carson nowhere considers the problem thus posed. Rather in applying my (18) (his (3)) he apparently takes relevant monopoly price-cost ratios simply to be such as actually obtain for individual monopolized products. All things considered, perhaps the moral is that we must after all view Carson's results as representing an application of my (18) to individual products, rather than composites. From that standpoint, however, I wonder if he is right in holding that monopoly price-cost ratios generally are less than 1.20. So far as (1) applies, the relevant ϵ, by implication, must generally be greater than 6.0. Especially under oligopoly that seems high. But then again, if Carson's (3) is applied to individual products and λ_i is always taken (as he takes it) as given by $\epsilon \geq \eta_i$, oligopoly is indisputably not covered by Carson's results in any case.[3]

In the calculation of monopoly welfare losses, it has come to be a usual practice to refer only to consumer's goods. Explicitly or by implication, intermediate products are treated simply as if they were consumer's goods. In my article I fell in with this procedure, but pointed out that so far as there are intermediate products, the relevant λ_i for any consumer's good is not that established for that good. Rather it is that λ_i, together with corresponding margins on intermediate products used in the production of the consumer's good; or rather those margins to the extent that they contribute to the cost of the consumer's good. Carson refers to this fact (fn. 2) and notes that welfare losses might possibly rise by as much as 40 percent when account is taken of pricing distortions for intermediate products. As far as I can see, however, he nowhere considers such distortions in deriving his "maximum estimate." To the contrary, his calculations only become the more questionable when those pricing distortions are accounted for. Thus the λ_i that is relevant to monopoly welfare losses, that is, the one that takes account of pricing distortions for intermediate products, must generally be higher than (1) might indicate, if ϵ is still understood (as is proper), as the elasticity relevant to pricing decisions for one another consumer's good. Hence, the relevant λ_i exceeds the price-cost ratio indicated by (1) even under monopolistic competition and pure monopoly. Also, there is now a further reason for the pertinent λ_i to vary independently of pertinent η_i. For purposes of calculating losses, the latter still relate to consumer's goods rather than intermediate products.

III

In calculating monopoly welfare losses, Dean Worcester, like Carson, wishes to aggregate. While I have urged that reference is properly made to price-cost ratios and demand elasticities for individual products, there are, according to Worcester, theoretic grounds for referring instead, at least in the case of an elasticity, to the output of an "industry."

We must distinguish two kinds of welfare loss under monopoly. In one, the community realizes its production possibilities, but owing to monopolistic pricing practices produces a suboptimal output mix. In the other, at least in some industries, different firms produce a single, homogeneous product at differing marginal costs. As a result, the community fails to realize its production possibilities.

---

[3] I refer below to the data on industry elasticities compiled by Dean Worcester in his comment on my article. While such elasticities cannot generally be used, as Worcester would have us use them, in the calculation of monopoly welfare losses, they are suggestive of relevant magnitudes of ϵ under oligopoly.

In the real world, the second kind of waste can occur under competition, at least in the "short run," as well as under monopoly, and where it occurs under monopoly, it often coexists with waste of the first sort. Conceptually, however, the two kinds of waste are distinct, and in empirical work on monopoly welfare losses, attention has usually been focused on waste of only the first sort, that associated with a suboptimal output mix. That is apparently the concern in all the calculations that I sought to evaluate in my original article. In trying to provide an analytic framework for the appraisal of such calculations, therefore, I simply assumed that the community is in fact on its production possibilities schedule. Only waste associated with a suboptimal output mix was considered.

As may not have been stressed sufficiently, however, from that standpoint aggregation to a certain point is not only not barred, but indicated. Thus, for optimality of the output mix, where different firms produce identical products necessarily only the total output of all firms together can matter. True, how that output is divided among the different firms may itself be a source of waste under monopoly, but that is the kind of waste where production possibilities are not realized rather than that where the output mix is suboptimal. It also follows that where reference is to optimality of the output mix and different firms produce identical products, it is the elasticity of demand for their total output that must be considered in calculating relevant losses.

All this must be kept in mind in considering Worcester's theoretic grounds for urging reference to industry rather than product demand elasticities in the calculation of monopoly welfare losses. Those grounds revolve around his analysis of two theoretic models of oligopoly. One of these, the "independent pricing" model, is of the familiar textbook sort where a dominant firm fixes prices monopolistically in the light of the aggregate demand for the output of the industry after making due allowance for supplies forthcoming from other firms that in effect act as perfect competitors. Although Worcester is not explicit, he clearly assumes here, as is often done, that the different firms are producing identical products. That is evident from his analysis of price determination in the industry, and also from his apparent supposition that, costs apart, it is immaterial for welfare how output is divided among the different firms.

It follows that at this point there can be no difference between Worcester and me on the principal question at issue. He contends and I of course agree that in the calculation of monopoly welfare losses, it is the elasticity of demand for the output of the industry that must be considered, so far as different firms produce identical products. Or rather I agree to the extent that the concern is with losses associated with a suboptimal output mix. In the case which Worcester considers, there evidently is also a shortfall from production possibilities, and Worcester might be read to mean that waste of both sorts together turns simply on the elasticity of demand for the industry's output. While a shortfall from production possibilities was not of concern in my original article, it should be observed that under dominant firm pricing such as in question, total waste properly viewed depends on not only the elasticity of demand for the industry's product, but the comparative cost schedules of different firms.

Worcester also considers a "collusive" model of oligopoly, where "each firm immediately matches the price of any other firm in the group, perhaps that set by a price leader." Under this model, we are told, "industry elasticities . . . are identical to firm elasticities and therefore are appropriate to the calculation of welfare loss. . . . " Here again Worcester is not entirely explicit regarding the comparative nature of the products of different firms, but one might wonder whether the collusive matching of prices that is envisaged does not already presuppose that those products are identical. In any event, his conclusion that it is the industry elasticity that must be considered in calculating losses is surely a nonsequitur on any other assumption.[4] Actually, Worcester himself apparently recognizes that his conclusion does not follow so far as there is "nonprice competition." That presumably prevails so far as there is product variety of any sort of interest to consumers. Hence, here too, I find no basis to disagree with him.

What, then, is in dispute? I am not sure, but Worcester may be assuming that oligopolistic firms characteristically produce identical products. That can hardly be so. As indicated, I understand oligopoly to prevail where a relatively limited number of firms produce more or less similar, though not necessarily identical, products. In fixing prices, at least some of the firms consider the impact of their actions on rivals. That I believe is a rather conventional conception. On that understanding, the products of different firms in an oligopolistic industry may be identical, but they are certainly not characteristically so. One may wonder whether they are typically so in oligopolistic industries generally, but in the calculation of monopoly welfare losses it is demand elasticities for consumer's goods that are of immediate concern. In respect of such goods, product variety is if anything virtually a hallmark of oligopolistic industries.

Possibly Worcester assumes that differences in products prevailing in such industries are immaterial to welfare, and that that is so even though consumers themselves value those differences. Such a standpoint is not exactly a rarity today, but it represents a major breach in the principle of consumers' sovereignty. That principle has always been presupposed hitherto in calculations of monopoly welfare losses.

While Worcester focuses on oligopoly, he contends that industry elasticities are the ones to refer to in the calculation of losses under monopoly generally. Apparently, that is held to be appropriate even under monopolistic competition understood in the usual sense that I explained above. I find Worcester very puzzling at this point, for he nowhere provides any support for such a view, and indeed sometimes seems to recognize its error. Needless to say, there is no basis here for me to shift from the standpoint I have taken on the question at issue.

Worcester has put us in his debt, then, by compiling, as he has done, systematic data on industry demand elasticities, but it is not possible to follow him in supposing they are applicable to the calculation of monopoly welfare losses. It also follows that his industry elasticities cannot readily be used, as Worcester uses them, as a benchmark for judging the plausibility of the hypothetical elasticities that I considered in making the illustrative calculations in my paper. Those elasticities are intended to relate to products, not industries.

In the light of diverse information that he also compiles on price-cost ratios, Worcester concludes that "We leave the matter of size of monopoly markups unresolved, but with considerable skepticism attached to values which require net income above competitive levels to exceed 15 percent of sales for more than a few years." I agree that the matter has been left unresolved.

While Worcester questions my hypothetical elasticities, a "much more serious objection" to my illustrative calculations is held to be that "most of the combinations of monopoly markup and elasticity" that I consider "are entirely inconsistent with profit-maximizing behavior." Apparently reference essentially is to the fact that I allow combinations of λ_i and η_i that fail to conform to (1) when ϵ is taken to equal η_i. As indicated in my reply to Carson, however, such a departure from (1) seems warranted where oligopoly prevails, for there, if (1) applies at all, ϵ is apt to differ from η_i, and sometimes markedly. Or rather, as we must now be careful to note, that is so except where oligopolistic firms produce identical products, which is the case on which Worcester implicitly focuses. Departures from (1) with $\epsilon=\eta_i$ are the more in order so far as η_i relates to consumers goods while λ_i properly reflects monopoly profit margins on intermediate products as well. Worcester neglects that aspect throughout.

---

[4] Should price-cost ratios of all firms be the same, however, and production be under conditions of constant costs, the output of the industry might be treated as a single composite even if the firms produce different products. See the author, p. 860.

Worcester holds that I even contemplate some equilibria that entail negative outputs of some products, or, what comes to the same thing, are beyond the community's production possibilities. The difficulty with Worcester's numerical demonstration of that odd result is that he erroneously takes a point elasticity of demand to apply over a wide range. If he will redo his calculations to correct that error, I think he will see that the community in fact remains on its production possibilities and so produces only positive outputs throughout, though under his assumptions no doubt it is pushed virtually to an extremity. More generally, all of my illustrative calculations were made to allow the community to realize its production possibilities both with and without monopolistic pricing in monopoly sectors.

IV

What follows regarding monopoly welfare losses? In presenting illustrative calculations on that matter in my original article, I of course did not mean to suggest that the more extreme cases considered were apt to be typical. With the information at hand, it simply did not seem wise to try to restrict narrowly the admissible possibilities. Carson's "maximum estimate" for monopoly welfare losses, however, is 3.2 percent of the national income. Even if that figure were accepted as an upper limit for the losses in question, it is worth noting that they could then be as much as thirty-two times as large as Harberger and Schwartzman found in calculations that I question. Such losses would also amount today to $45 billions. But, despite Carson's ingenious computations, it is difficult to avoid the conclusion that an upper limit for monopoly welfare losses still remains to be fixed. It does not seem possible either to join Worcester in thinking that "The time is surely close at hand for economists to accept the research findings that welfare losses due to enterprise monopoly are small in the American economy. On the evidence, industry approximates the competitive model. . . . "

In sum, a principal moral of my 1973 paper was clearly that, contrary to Harberger, Schwartzman, and others, monopoly welfare losses could easily be quite consequential. I also urged, however that more research is needed on the important question at issue. Illuminating as the comments of Carson and Worcester are, I must conclude that both morals are still indicated.

The Economics of the Network-Affiliate Relationship: Comment

By DANIEL A. GRAHAM AND JOHN M. VERNON*

In a recent issue of this *Review*, Stanley Besen and Ronald Soligo (hereafter, B-S) presented an ingenius graphical analysis of the economics of network-affiliate relationship in the television broadcasting industry. The purpose of this note is to correct several errors in their analysis, to "adjust" their basic diagram in a way that makes certain results much more transparent, and to demonstrate that the relaxation of one assumption invalidates one of their major conclusions.

I. The Besen-Soligo Model

We begin by describing the analysis of B-S and our extension of it. The focal point is the relationship between a network and a "representative" affiliate for the case in which the number of local stations exceeds the number of networks. In this context B-S assume that the network has monopsony power in the purchase of *cleared time* from the affiliate. The affiliate is viewed as supplying a service to the network, namely, the broadcasting of network programs, and the total supply of this service is referred to as cleared time. Affiliates are compensated in two ways: 1) by receiving a share of the revenue that the network collects from its sale of advertising time on network programs, and 2) by receiving a share of the total time available for commercials within each network program. (The affiliate retains all revenue from its sale of this commercial "spot time.")

For the ith hour of programming, the affiliate can calculate that value of p (the fraction of network advertising revenues returned to the affiliate) for which it would be indifferent between clearing the time to the network and using the time for local programming. This break-even value of p is labeled p_i by B-S and is given by the condition:

$$p_iA_i + S_i = V_i \tag{1}$$

where

$A_i \equiv$ network advertising revenues for the ith hour[1]

$S_i \equiv$ affiliate advertising revenues from the sale of spot time during the ith hour

$V_i \equiv$ net revenue that could be earned by the affiliate by broadcasting local programming during the ith hour.

The B-S analysis may be clarified somewhat if we assume that the network and affiliate can sell commercial time on a given program for the same price[2] and if we let β_i denote the ratio of spot time to network advertising time during the ith hour. We may then write

$$A_i = T_i/(1+\beta_i)$$
$$S_i = \beta_iT_i/(1+\beta_i)$$

where $T_i =$ the total value of advertising time on the ith hour of network programming. If we further assume, as in fact appears to be the case,[3] that β_i does not vary from hour to hour, then equation (1) may be rewritten as

$$p_i = (1+\beta)V_i/T_i - \beta \tag{2}$$

where β denotes the common value of the β_i.

The heart of the B-S analysis is the affiliate's supply curve of cleared time. To construct this curve, array program hours in order of increasing p_i or, equivalently, in order of increasing V_i/T_i. The supply curve is then obtained as the curve described by the coordinate pairs $(\sum_{j=1}^{i} A_j,\ \hat{p}_i)$. This supply curve relates the quantity of cleared time supplied (measured in terms of the associated value of network advertising) to the revenue-share p set by the network.

---

* Associate professor and professor of economics, respectively, Duke University. We are indebted to Merton Peck for helpful comments on an earlier draft.

[1] This is not total network advertising receipts but only that portion attributable to the region serviced by the particular affiliate.

[2] Notice that both affiliate and network are selling what is inherently the same commodity, e.g., a "New York, Gunsmoke, viewer minute."

[3] See Roger Noll, Merton Peck, and John McGowan, p. 61.

Such a supply curve is illustrated by the curve *BC* in Figure 1. If the network should set p_0, for example, the affiliate would clear all hours to the left of A_0 since p_0 exceeds the break-even $\hat{p}_i$ for each of these hours. In such circumstances B-S point out that the network's share of advertising revenues would be area *II* and the affiliate's share would be the sum of areas I_a and I_b.

They also point out that the net profit or quasi rent to the station from network affiliation is given by the sum of areas I_a and *III*. Although this last observation is correct, it can be made much more transparent by adding a horizontal line to their diagram at a distance β below the horizontal axis. Regarding this line βW as the new horizontal axis, we may interpret the area under the supply curve and to the left of A_0 as the opportunity cost to the affiliate of supplying A_0 of cleared time. This can be seen as follows. The ith hour accounts for network advertising revenues equal to A_i or, in Figure 1, for that portion of the horizontal axis corresponding to the width of rectangle *FR*. Since the height of this rectangle from *T* to *R* is equal to β or S_i/A_i and since the width is equal to A_i, the area from *T* to *R* must be equal to S_i. Recalling equation (1), to break even on this hour $\hat{p}_i A_i$ (the area of the rectangle from *J* to *T*) plus S_i (the area from *T* to *R*) must be equal to V_i. Thus, by construction, the area from *J* to *R* must be V_i, the opportunity cost to the affiliate of clearing the ith hour. Summing over the total amount of cleared time A_0, we obtain the area under *BC* and above the new axis βW as the total opportunity cost. It should now be clear that the total revenue received by the affiliate from its share of network advertising and from its sale of spot time (the area of rectangle $\beta p_0 MW$) exceeds the total opportunity cost by the sum of areas I_a and *III* (the affiliate's quasi rent).

The addition of the βW line would have enabled B-S to avoid an error of interpretation. On page 263 they refer to the area under the supply curve and above ***their*** axis OA_0 (comparable to area I_b in Figure 1) as the profits on hours to the right of *X* that "the station would earn if it were an independent station." This is clearly in error since it understates the true opportunity cost by an amount equal to the value of the spot time for these hours.

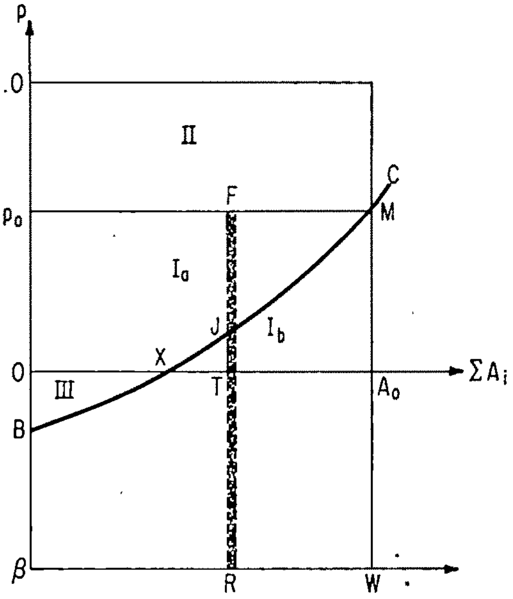

FIGURE 1

II. The Nondiscriminating Monopsonist Solution

The B-S solution to the network profit-maximization problem is reproduced in Figure 2. They assume that the marginal cost of supplying an additional program to the affiliate is zero. Thus profits are maximized when the curve marginal to the supply curve intersects the horizontal line at $p=1$. This point is characterized by the fact that the marginal revenue product to the network of the last program hour is equal to the zero marginal cost of programming. The network maximizes profits, therefore, by setting a revenue-share price equal to p_e and by purchasing A_e of cleared time from the affiliate.

There appear to be two errors in this

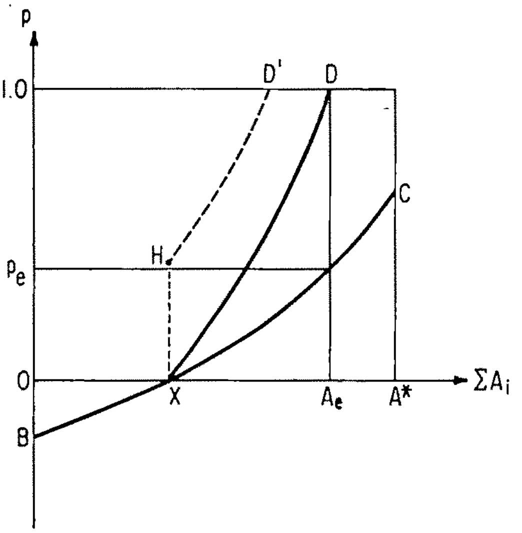

FIGURE 2

analysis. First, B-S argue that the curve "marginal to" BC is given by XD:

> The curve XD does not extend below the horizontal axis because the network will have programs of value OX cleared even if $p=0$. If the network were permitted to make p negative, i.e., to charge the affiliate for a cleared program, the curve marginal to the supply curve would begin at B. [p. 262, fn. 8]

The fact that negative p values are not allowed, however, has nothing to do with where the marginal curve begins. The correct marginal curve is essentially the same as the marginal outlay curve of a monopsonist confronting a factor supply curve subject to a minimum factor price constraint. In Figure 2 the correct curve coincides with the horizontal axis from O to X, skips discontinuously from X to H, and coincides with the dashed curve HD' thereafter. If negative p were allowed, HD' would extend leftward to point B. This, of course, does not alter the fact that the correct marginal curve must "pass through" point H in either circumstance.

The second deficiency in the B-S analysis involves the assumption (pp. 260, 262) that all network programming costs are fixed and that the marginal cost of supplying an additional hour of existing programming is therefore zero. There are at least two problems with the assumption of zero marginal programming costs.

First, according to B-S, Figure 2 depicts a *representative* affiliate. Presumably, therefore, we can regard *all* affiliates as reaching an equilibrium relationship with the network characterized by the intersection of the marginal curve and the horizontal line at $p=1$ (where marginal programming costs are zero). But this implies that the network *overinvested* in programming. That is, if the marginal revenue product to the network of the last hour cleared by a representative affiliate (and thus by *all* affiliates) is to be zero, then the network would have been better off had it not invested in that last hour of programming.

The second problem with the assumption of zero marginal programming costs is that it is conceptually misleading. Zero marginal programming costs imply fixed programming costs during the period in which the network sets its pricing policy concerning affiliates. However, at repeated intervals the network must enter into agreements to purchase programs. At such times the network must answer questions of the sort, "How much is program ______ worth?" The answers to such questions are, of course, dependent upon the particular pricing policy that the network will be able to employ vis-à-vis its affiliates. The network must, therefore, determine its optimal pricing policy toward affiliates interdependently with the determination of its demand for programs.

We would argue, therefore, that the actual solution of the network pricing problem would be made at the time that programs are purchased and would involve setting a revenue sharing price for affiliates such that the marginal revenue product to the network of the last hour is equal to the nonzero cost of purchasing that hour of programs. Since, as Noll, Peck, and McGowen indicate (p. 66), the cost of programs may amount to 30 percent of total network advertising revenue, the difference between this solution and that of B-S may be substantial.

One further aspect of the nondiscriminating monopsonist solution should be mentioned. While B-S admit that the proportion (β) of commercial time given to an affiliate is an important dimension of the affiliation agreement (p. 259), they assume, presumably for purposes of simplicity, that this proportion is fixed and not subject to change by the network (p. 260). While, as we shall see, this assumption has no appreciable effect upon the nondiscriminating monopsonist solution, it does have a rather significant effect if the network can discriminate. Turning first to the nondiscriminating case, we observe that equation (2) can be rewritten as

$$\frac{p_i+\beta}{1+\beta}=\frac{V_i}{T_i}$$

This means that if the network were to set any p, β combination satisfying

$$\frac{p+\beta}{1+\beta}=\frac{V_{i'}}{T_{i'}}$$

a total of i' hours of cleared time would be supplied by the affiliate. Thus $\gamma\equiv(p+\beta)/(1+\beta)$ can be regarded as the parameter which determines the supply of cleared time and the supply function can be written

$$t=f(\gamma)$$

where $t\equiv$supply of cleared time (demand for network programming) by affiliate measured in hours. The network profit maximization problem thus becomes

$$\max_{p,\beta}\pi\equiv\sum_{i=1}^{f(\gamma)}[(1-p)A_i-C_i]$$

where $C_i\equiv$the cost to the network of obtaining the ith hour of programming.[4]

Substituting for A_i yields

$$\pi=\sum_{i=1}^{f(\gamma)}[T_i(1-p)/(1+\beta)-C_i]$$
$$=\sum_{i=1}^{f(\gamma)}[T_i(1-\gamma)-C_i]$$

The network problem of selecting p and β so as to maximize profit thus reduces to one of selecting γ. Denoting this profit maximizing γ by γ^* it follows that the network would be indifferent among all p, β combinations which satisfy

$$\frac{p+\beta}{1+\beta}=\gamma^* \tag{3}$$

Since all such pricing policies have already been shown to entail the same supply of cleared time, the ability to set β adds nothing of interest to the solution. Given an arbitrary β the network would do just as well by simply solving equation (3) for the associated p; the total supply of cleared time, network profit, and affiliate profit would remain invariant under all such solutions.

III. The Discriminating Monopsonist Solution

B-S show that the ability of the network to discriminate, i.e., to extract portions of the quasi rents that accrue to affiliates, hinges upon the use of two devices: 1) *uncompensated time*, a two-part pricing scheme in which the network sets a zero price for an initial number of hours cleared and a positive price for all subsequent hours; and 2) *option time*, a scheme in which affiliates are required to clear a certain minimum number of hours in order to maintain their affiliation.

Using graphical analysis they argue that while the use of uncompensated time allows the network to capture a portion of the quasi rent, it is necessary for the network also to use option time if it wishes to extract all rents. Referring to the Federal Communications Commission ban on the use of option time B-S conclude: "The bar against option time, if it is effective, may result in some quasi rents being retained by the affiliate" (p. 265). As support for this conclusion, they go on to cite the empirical finding that network affiliates are more profitable than independents when other determinants of profitability are taken into account.

The B-S argument can be seen by reference to Figure 3. Here point $\bar{A}$ is chosen so that area I is equal to area II. Suppose now that the network wants to buy A^* of cleared

---

[4] Here we assume that all n affiliates are alike. Thus C_i, the program cost for one affiliate, can simply be regarded as one nth of the total program cost.

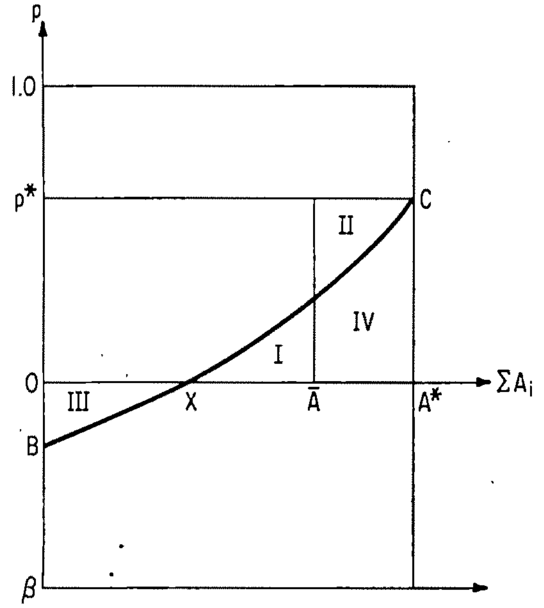

FIGURE 3

time from the affiliate. By setting p equal to zero for the first $\bar{A}$ of cleared time and by setting p equal to p^* for all subsequent hours the network would render the affiliate indifferent between clearing X hours and A^* hours. Thus the network would capture the quasi rents on all hours to the right of X. As B-S point out, however, quasi rents equal to area *III* still accrue to the affiliate. The network, moreover, is apparently unable to capture this remaining rent since increasing the amount of uncompensated time would induce the affiliate to clear only X hours and since reducing p below p^* on subsequent hours would also induce the affiliate to clear less than A^* hours. These considerations are the basis for the B-S conclusion that the use of option time is necessary to capture the remaining quasi rent.

We find this conclusion to be unwarranted, however, since it depends crucially upon the simplifying assumption that the network cannot control β. If the network can in fact determine β then it can extract all the quasi rent with the use of uncompensated time alone. This is done by reducing the value of β. Such reductions in β shift the affiliate supply curve in such a way that point X moves leftward. By continuing until point X coincides with the origin, the network can eliminate area *III* entirely. It can then determine $\bar{A}$ so that quasi rents on *all* hours are captured by the network. More precisely, by setting

$$\beta^* = \frac{V_1}{T_1 - V_1} > 0$$

it follows from equation (2) that

$$p_1 = (1 + \beta^*)\frac{V_1}{T_1} - \beta^* = 0$$

This choice of β thus produces an affiliate supply curve which intersects the horizontal axis at the origin. Now suppose that the network wishes to clear t^* of programs measured in hours. This requires that the network set

$$p^* = (1 + \beta^*)\frac{V_{t^*}}{T_{t^*}} - \beta^*$$

By then selecting that number of uncompensated hours which equates the quasi rent on subsequent hours to the losses on the uncompensated hours, the network can capture all quasi rent without recourse to option time.

The Economics of the Network-Affiliate Relationship: Reply

By STANLEY M. BESEN AND RONALD SOLIGO*

Daniel Graham and John Vernon's (G-V) comment on our paper raises four points: 1) that we have erred in the construction of the curve marginal to our "supply" of time schedule; 2) that we have mistakenly identified the area under the supply curve as the return which a network affiliate would have received had it remained an independent station; 3) that if the network regards the marginal cost of supplying a program to an additional affiliate as zero that this will lead to an oversupply of programming; and 4) that when our analysis is extended to permit variations in the distribution of advertising time between the network and the affiliate that one of our conclusions, that the ban on option time permits the affiliate to earn above normal profits, is vitiated.

We are grateful to G-V for pointing out the technical slip in the construction of the curve marginal to the supply schedule and for indicating the inaccuracy in our description of area under the supply curve. We would point out only that while our description was inaccurate, our analysis was correct.

G-V's third point is not correct. They are clearly right that the network must determine whether it should produce a program at all. And, clearly, for the network to be willing to do so the sum of the returns it gets from each of the stations that carry the program (the network share of advertising revenue minus the payment to the affiliate) must exceed the cost of carrying the program. But, contrary to their claim, the network need not have "*overinvested* in programming" even " . . . if the marginal revenue product to the network of the last hour cleared by a representative affiliate (and thus by *all* affiliates) is . . . zero. . . . " (p. 1034).

To see why this is so it is necessary only to recognize that the array of programs according to the sharing ratio which will induce the affiliate to accept programs can and in general will be different for different stations. The relative attractiveness of a given network program and its nonnetwork programming alternatives is likely to differ from market to market because, for example, audiences tastes differ. If these differences exist, the return to the network from the carriage of the marginal program by each affiliate *can* be zero while all programs in the network schedule are profitable. A program which is marginal for one station will be inframarginal for others and there will be contributions to network profits from the carriage of the program by all stations for which the program is inframarginal.

G-V's analysis of this point is misleading in one important respect. It is generally not possible to write down an equation such as their profit-maximizing equation since it is not possible to know on the basis of data from a single station alone what share of the cost of a program it should bear if the network is to maximize its profits. For the case cited in G-V's footnote 4 in which all affiliates are identical, equal apportionment of cost gives the correct answer, but in general it will not be possible to employ this procedure.

While G-V are correct that the network must earn positive profits on each program, their attempt to take production costs into account at the time of establishing the terms of the affiliation contract runs the risk that the network will not produce a program which would increase its profits. The approach that we suggest, that the network first decide what its payment will be to each affiliate *if a program is produced* and then decide whether the program should be produced at all, always yields the correct answer

---

* Professors of economics, Rice University. We wish to acknowledge financial support from National Science Foundation, grant GI 38909.

while the proposed G-V procedure does not.

As for point 4), G-V are correct that the network can, by reducing the proportion of advertising time during which an affiliate can sell advertising, shift the supply curve of programming upward, thus increasing network profits while leaving the amount of programming accepted unchanged. This represents an interesting extension of our model. We would, however, raise two points concerning it. First, the policy requires that the networks increase the proportion of network advertising revenue p paid to affiliates to get them to clear the entire network schedule.[1] But, as we pointed out in our paper (p. 264), there seems to exist an informal upper bound on p which is designed to make it possible for nonnetwork program suppliers to have access to the time of network affiliates. If the increase in p required by the reduction in station advertising time would cause it to exceed this limit, it may still prove impossible for the network to get all of a station's quasi rents. Second, since presumably one of the objectives of the ban on option time was to increase station profits, the Federal Communications Commission might not be terribly receptive to changes in network behavior which offset the effects of the ban, especially when the objective of the change is likely to be transparent. The basic thrust of G-V's point 4) deserves emphasis, however. When the regulated firm has many degrees of freedom, it will often be able to partially or totally frustrate the efforts of the regulators.

[1] Network profits increase, nevertheless, because the *total* amount of network advertising revenue increases.

NOTES

On March 14, 1975 the Executive Committee of the American Economic Association approved the following changes in the financial operation of the *American Economic Review* and *Journal of Economic Literature.*

a) The discontinuance of free reprints/offprints to authors of material appearing in the *American Economic Review* and *Journal of Economic Literature.* Reprints/offprints will continue to be sold at prices which cover the relevant costs. This change will begin with the December 1975 issues.

b) A differential submission fee for authors who are not members of the American Economic Association. As of July 1, 1975, the submission fee for manuscripts submitted to the *American Economic Review* is now fifteen dollars ($15) for members and thirty dollars ($30) for nonmembers.

c) A postage surcharge for mailing of material outside the United States. This surcharge will equal the difference between mailing costs inside and outside the United States. It will be added to new subscription and membership bills January 1, 1976.

d) A page charge for articles, shorter papers, notes, comments, and replies published in the *American Economic Review* and in the *Journal of Economic Literature.* The charge will be twenty-five dollars ($25) per printed page, and is in effect with manuscripts accepted after July 1, 1975.

The page charge is payable by the institution or granting agency supporting the research. Payment of this charge is not a prerequisite for publication, nor are authors expected to pay these charges themselves. Moreover, articles are accepted without prior knowledge of any financial support which the author may have at his disposal. If the author or his institution cannot pay the page charge, it is no obstacle to publication. The purpose of the page charge is to take advantage of willingness of sponsoring agencies in the federal and state governments and private foundations to defray the expense of publishing research in scholarly journals. Page charges are regarded as a legitimate item in the budgets of research grants, and journals in other disciplines have taken advantage of this source of revenue for some time.

Annual Meeting Placement Service

The Placement Service at the 1975 annual meetings of the Allied Social Science Associations in Dallas will begin operation on December 27, the day before sessions begin. Applicants and employers will be able to attend more sessions with a day set aside entirely for labor market transactions. The Placement Service will continue during the other days of the annual meetings, but hopefully at a less frantic pace than in previous years. This service will be located at the Convention Placement Center in the Dallas Convention Center. It will be open from 10:00 A.M. to 5:00 P.M., December 27; 8:30 A.M. to 5:00 P.M., December 28–29; and 8:30 A.M. to 12:00 noon December 30.

For your convenience the National Registry for Economists is offering a pre-convention registration service. Forwarding your application or position(s) to the Registry prior to the meetings will expedite service at the Convention Placement Center. Employment applications and listings of available positions will also be accepted from those who cannot attend the meetings and will be made available for review by the participants. Immediately upon arrival at the convention, registrants should report to the Convention Placement Center so that their pre-convention registration can be activated. Forms may be obtained from the National Registry for Economists, Illinois State Employment Service, 40 West Adams Street, Chicago, Illinois 60603. They must be completed and returned to the National Registry prior to December 5, 1975.

The program committee for the September 1976 meetings of the American Economic Association invites contributed papers. These will be screened by committee members and notification of acceptance or rejection will be sent by March 1, 1976. Prospective contributors are urged not to submit similar papers to the American Economic Association, the Econometric Society, or other associations. Contributed papers for the American Economic Association sessions should be of the type that would not be considered primarily for presentation to the Econometric Society. Those interested in submitting papers for consideration are invited to send abstracts *not later than* February 1 to Lawrence R. Klein, Department of Economics, University of Pennsylvania, Philadelphia, Pennsylvania 19104.

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history, and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The deadlines for applications to be received in the office of the American Economic Association are: for meetings scheduled between June and September, February 15; for meetings scheduled between October and January, June 15; for meetings scheduled between February and May, October 15. Application forms may be obtained from Rendigs Fels, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

The Joint Committee on Soviet Studies and the Joint Committee on Eastern Europe of the American Council of Learned Societies and the Social Science Research Council wish to draw attention to Grants Programs in Soviet Studies and East European Studies. The programs include Grants for Post-Doctoral Research, Grants for Study of East European Languages, Grants in Support of Conferences, and Travel Grants to International Conferences Abroad. For details of eligibility and information which *must* be supplied in requesting application forms, request an announcement brochure from Office of Fellowships and Grants, American Council of Learned Societies, 345 E. 46th Street, New York, NY 10017.

As of July 1, 1975, the *Journal of International Business Studies*, the official journal of the Academy of International Business, is being edited and published at the Rutgers School of Business. All persons engaged in the preparation of high quality advanced scholarly research papers in the areas of international business, management, institutions, economics, and policy are invited to submit manuscripts in three copies for editorial consideration and possible publication to Professor Robert Vambery, Rutgers University, Graduate School of Business, Newark, NJ 07102.

Omicron Delta Epsilon, the International Honor Society in Economics, invites the submission of entries for the eighth year of the Irving Fisher Graduate Monograph and Frank W. Taussig Award Undergraduate Competitions. The Fisher Award consists of $1,000 and publication as a book by Princeton University Press, subject to approval of its editorial board. In addition, the winner will be invited to submit a paper based on the winning entry to the *American Economic Review*. The recommendations of the Final Selection Board of the Competition will be considered by the *Review* in the refereeing process. All finalists will be invited to submit a paper for publication in *The American Economist*. The Taussig Award consists of $100 and publication in *The American Economist*. Entries for the Fisher Award should be submitted to Departmental Selection Committees by January 1, 1976 and entries for the Taussig Award by May 15, 1976. They will be judged by the International Editorial Board and finalists by the Final Selection Board, consisting of Professors William J. Baumol, Frank H. Hahn, Robert M. Solow, Arnold Zellner, and Egon Neuberger (editor). For more information, write Professor E. Neuberger, Editor, Economic Research Bureau, State University of New York, Stony Brook, NY 11794.

Nijenrode Congress: Call for Papers

From August 25 to 27, 1976, a Congress on Decision Making in Business will be held at The Netherlands School of Business in Breukelen, The Netherlands. Papers are invited in the various subdivisions of management studies: accounting, finance, marketing, organization, law, environment, ethics, psychology, sociology, communication, economics, O.R., etc. The Congress will consist of two sessions: a one-day symposium, during which prominent speakers will address and take part in discussions with a large gathering of participants; and a two-day research seminar, consisting of parallel sessions devoted to particular themes or topics. Those who wish to present papers are invited to send a resume to Dr. C. van Dam, The Netherlands School of Business, Nijenrode, Breukelen, The Netherlands. Preliminary drafts of papers will be needed in triplicate before February 1, 1976.

The S. S. Huebner Foundation for Insurance Education is initiating an experimental program of grants to support scholarly research in the field of risk and insurance. Full-time faculty at colleges and universities in the United States and Canada are eligible to apply for grants. Applicants must hold a doctoral degree or be a fellow of an actuarial society. Proposals will be considered for projects in all areas relating to insurance including, but not limited to, the role of insurance companies in the capital markets, the theory of consumer demand for insurance, and social security and other governmental insurance programs. Awards of up to $10,000 are available, and grant applications are due by February 1, 1976. For further information contact Dr. J. David Cummins, Research Director, S. S. Huebner Foundation for Insurance Education, W-133 Dietrich Hall/CC, University of Pennsylvania, Philadelphia, Pa. 19174.

Call for Papers

The XIV International Symposium on the Application of Computer Methods in the Mineral Industries (*APCOM*) will be held at the Pennsylvania State University October 4–8, 1976. The program committee invites abstracts of papers to be considered for presentation at the symposium. The abstract must not be more than 500 words, and should be mailed to reach Dr. R. V. Ramani, 116 Mineral Industries Building, University Park, Pa., 16802, U.S.A., not later than January 15, 1976. Sessions on the following topics, as they pertain to the mineral industries, are being planned: national and international planning for raw materials; investment planning in multinational companies; health, safety, environment and manpower planning; computers in coal and mineral processing; exploration and ore reserve estimation; production planning and control; management information systems; industrial case studies; automation and process control; economic modeling of the mineral sector. Those interested in receiving future mailings should send their names and addresses to Dr. R. V. Ramani.

The Social Science Research Council announces two postdoctoral fellowships in criminal justice indicators for the academic year 1976–77. The program provides an opportunity for fellows to work on analysis and indicator development projects of their own design, using statistical data from the Law Enforcement Assistance Administration or other sources. In selecting fellows, the subcommittee will give priority to projects emphasizing the measurement of change and the development and analysis of time-series, particularly series based on replicated surveys. There are no application forms. Applicants are asked to submit resumes, copies of publications, and project proposals (indicating the questions to be investigated, the data base to be used, and the plan of analysis) no later than January 31, 1976, to David Seidman, SSRC Center for Social Indicators, 1755 Mass. Ave., N.W., Washington, D.C. 20036 (202+667-8884).

April 21 through 24, the Society of Government Economists and the Economic Development Administration of the Commonwealth of Puerto Rico will hold a conference on economic development in San Juan, Puerto Rico. Sessions on financial incentives and economic development techniques will focus on problems relating to transportation, health, energy, education, and labor. Sessions are also planned on data requirements, economic models, socio-cultural barriers to development and research. For program information write to Tom Herrick, Long Island University, Brooklyn, New York, or Lewis Smith, Director of Planning and Research, Economic Development Administration, San Juan, Puerto Rico. Registration information can be obtained by writing Martin Stein of the Maryland Department of Transportation. P.O. Box 8755, Baltimore-Washington International Airport, Baltimore, Maryland 21240.

The fourth national conference sponsored by the Intersociety Committee on Transportation will be held in Los Angeles, California, July 18–23, 1976. Papers will be presented covering all aspects and modes of ground, air, and water transportation. Planned sessions include air cargo, highway and rail freight, passenger modes, water transportation, mass transit, pipelines, multimodal, transportation of energy, economics and costs, policy and planning, command and control, environmental impact, energy considerations, information systems, design and engineering, operations. Authors are invited to send abstracts of 300 words or more on these or other related areas by December 15, 1975 to J. F. Courtney, Vought Systems Division, P.O. Box 5907, Dallas, Texas 75222.

A Committee on the Social Sciences in the National Science Foundation has been appointed by the National Academy of Sciences in response to a request from the Director of the National Science Foundation. The committee has been asked to submit a report to NSF that includes recommendations regarding research areas and activities that should be supported in the future. The committee invites members and readers to comment on and offer suggestions for promising directions of social science research and activities that NSF should consider strengthening or initiating. Since the committee will begin to draft its report late this year, please write within the next few weeks to Herbert A. Simon, Chairman, National Academy of Sciences, JH 818, 2101 Constitution Avenue, Washington, D.C. 20418.

Deaths

Harry Gunnison Brown, professor emeritus of economics, University of Missouri, former acting dean; and past president of the Midwest Economic Association, Mar. 18, 1975.

Barbara Carbaugh, Columbus, Georgia, May 17, 1975.

Thor Hultgren, department of economics, University of Wisconsin-Milwaukee, July 31, 1975.

Retirements

Harry T. Oshima, professor of economics, University of Hawaii, Dec. 30, 1974.

Spencer D. Pollard, economics department, University of Southern California.

*Visiting Foreign Scholars**

Geoffrey M. Heal, University of Sussex, England: visiting professor of economics, Yale University, fall 1975.

David F. Hendry, London School of Economics: visiting associate professor of economics, Yale University, fall 1975.

Hiromi Ishigaki: Fulbright-Hays scholar, American Graduate School of International Management, Sept. 1, 1975.

Hartmut Keil, University of Munich: visiting assistant professor, University of Wisconsin-Madison, 1975–76.

Rolf R. Mantel, University of Buenos Aires and Institute Torcuato Di Tella, Argentina: visiting professor of economics, Yale University, July 1975.

Robert Marris, University of Cambridge: visiting professor, department of political economy, Johns Hopkins University, Sept. 1–Dec. 31, 1975.

Ana Maria Martirena-Mantel, University of Buenos Aires and Institute Torcuato Di Tella, Argentina: visiting professor of economics, Yale University, July 1975.

Mihai N. Tarca, University of Iasi, Romania: visiting lecturer, University of Wisconsin-Madison, 1975–76.

Promotions

Bernard E. Anderson: associate professor of industry, Wharton School, University of Pennsylvania, July 1, 1975.

Sven W. Arndt: professor of economics, University of California, Santa Cruz, July 1, 1975.

June Axinn: professor of social welfare, University of Pennsylvania, July 1975.

Sara S. Berry: associate professor, department of economics, Indiana University, July 1, 1975.

Joseph P. Cain: assistant professor of econometrics, department of systems management, Air Force Institute of Technology, School of Engineering, Wright-Patterson Air Force Base, July 15, 1974.

William F. Campbell: professor of economics, Louisiana State University, Aug. 1975.

Robert D. Coston: associate professor of economics, Georgia Southern College, July 1975.

W. Patton Culbertson: associate professor of economics, Louisiana State University, Aug. 1975.

Emit B. Deal: associate professor of economics, Georgia Southern College, July 1975.

Moheb A. Ghali: professor of economics, University of Hawaii, July 1, 1975.

John M. Godfrey: senior financial economist, Federal Reserve Bank of Atlanta, May 1, 1975.

Patrick J. Gormely: associate professor, department of economics, Kansas State University, fall 1975.

Charles P. Gratto: professor of economics, Iowa State University, July 1, 1975.

Kenneth V. Greene: associate professor of economics, State University of New York, Binghamton, Sept. 1, 1975.

David H. Hammond: associate professor of economics and extension resource development specialist, Iowa State University, July 1, 1975.

Robert E. Hicks: professor, department of economics, Florida Technological University.

George E. Hoffer: associate professor of economics, Virginia Commonwealth University, July 1975.

Robert C. Hsu: associate professor of economics, Clark University, Sept. 1, 1975.

David B. Johnson: professor of economics and director of Division of Research, Louisiana State University, Aug. 1975.

Richard H. Keehn: associate professor of economics, University of Wisconsin-Parkside, Sept. 1974.

Thomas E. Kennedy: assistant professor, department of economics, Kansas State University, fall 1975.

Kwan S. Kim: associate professor, University of Notre Dame, 1975–76.

Taeho Kim: associate professor, American Graduate School of International Management, Sept. 1, 1975.

Harvey E. Lapan: associate professor of economics, Iowa State University, Sept. 1, 1975.

William H. Leahy: professor, University of Notre Dame, 1975–76.

Youngil Lim: professor of economics, University of Hawaii, July 1, 1975.

John J. McGowan: vice president, Charles River Associates, Inc., Cambridge, Mass.

Louis J. Maccini: associate professor, department of political economy, Johns Hopkins University, July 1, 1975.

Ronald E. Müller: associate professor, department of economics, American University, Sept. 1, 1975.

Phillip J. Nelson: professor of economics, State University of New York, Binghamton, Sept. 1, 1975.

Alan L. Olmstead: associate professor, department of economics, University of California, Davis, July 1, 1975.

Dennis M. O'Toole: associate professor of economics, Virginia Commonwealth University, July 1975.

Russell G. Pounds: associate professor of economics, Iowa State University, July 1, 1975.

Bertrand M. Renaud: professor of economics, University of Hawaii, July 1, 1975.

J. David Richardson: associate professor of economics, University of Wisconsin-Madison.

James A. Richardson: associate professor of economics, Louisiana State University, Aug. 1975.

Louis A. Rose: associate professor of economics, University of Hawaii, July 1, 1975.

Robert Schafer: associate professor of city planning, department of city and regional planning, Harvard University, July 1, 1975.

Stephen A. Schneider: assistant professor of management and industrial relations, department of management, Wharton School, University of Pennsylvania, July 1, 1975.

Wayne J. Shafer: associate professor, department of economics, Wayne State University, Sept. 1975.

Calvin D. Siebert: professor of economics, University of Iowa, Aug. 1975.

John J. Siegfried: associate professor of economics, Vanderbilt University, Sept. 1975.

V. Kerry Smith: professor of economics, State University of New York, Binghamton, Sept. 1, 1975.

William F. Steel: associate professor of economics, Vanderbilt University, Sept. 1975.

Dale Vorderlandwehr: associate professor, American Graduate School of International Management, Sept. 1, 1975.

Robin J. Walther: assistant professor, economics department, University of Southern California.

Gary M. Walton: professor, department of economics, Indiana University, July 1, 1975.

Jane White: associate professor of business administration, Georgia Southern College, July 1975.

Norman K. Womer: associate professor of economic analysis, department of systems management, Air Force Institute of Technology, School of Engineering, Wright-Patterson Air Force Base, Jan. 1, 1975.

Administrative Appointments

Robert E. Baldwin: chairman, department of economics, University of Wisconsin-Madison.

Whewon Cho: chairman, department of economics and finance, Tennessee Technological University, Sept. 1, 1975.

Clifford D. Clark: president, State University of New York, Binghamton, Mar. 26, 1975.

Robert D. Coston: head, department of economics, Georgia Southern College, Sept. 1975.

John V. Craven: chairman, economics department, Middlebury College, Aug. 1975.

Eugene A. Diulio: chairman, department of economics, Fordham University.

Marshall Geer III: dean of faculty, American Graduate School of International Management, Sept. 1, 1975.

Robert E. Herman: chairman, department of economics, Nassau Community College, Sept. 1975.

John E. La Tourette: acting provost for graduate studies and research, State University of New York, Binghamton, June 2, 1975.

Charles L. Leven: chairman, department of economics, Washington University (St. Louis), July 1, 1975.

Alvin M. Marks: chairman, department of world business, American Graduate School of International Management, Sept. 1, 1975.

John A. Sawyer: director, Institute for the Quantitative Analysis of Social and Economic Policy, University of Toronto, July 1, 1975.

Howard M. Wachtel: chairman, department of economics, American University, June 1, 1975.

William H. Waldorf: acting chairman, department of economics, State University of New York, Binghamton, June 2, 1975.

Ray M. Ware: chairman, department of administration and economics, Transylvania University.

Frederick S. Weaver: dean, School of Social Science, Hampshire College, July 1, 1975.

Murray L. Weidenbaum: director, Center for the Study of American Business, Washington University (St. Louis), Jan. 1, 1975.

Charles K. Wilber, American University: chairman, department of economics, University of Notre Dame, fall 1975.

Appointments

Morris Allen: associate professor of management, American Graduate School of International Management, Sept. 1, 1975.

Robert J. Barro, University of Chicago: professor of economics, University of Rochester, July 1, 1975.

Michael C. Barth, Department of Health, Education, and Welfare: visiting associate professor of economics; research associate, Institute for Research on Poverty, University of Wisconsin-Madison.

Romeo M. Bautista: visiting research fellow, National Bureau of Economic Research, Aug. 1975.

Yoav Benari: economist, Foreign Research Division, Federal Reserve Bank of New York, Sept. 1975.

Lynn Bergold, Southwestern Publishing Co.: special lecturer, North Carolina State University, fall 1975.

H. H. Boggs: assistant professor of world business, American Graduate School of International Management, Sept. 1, 1975.

W. Richard Bossert: assistant professor of world business, American Graduate School of International Management, Sept. 1, 1975.

Ivy Broder: assistant professor, department of economics, American University, Sept. 1, 1975.

Albert E. Burger, Federal Reserve Bank of St. Louis: adjunct professor, St. Louis University, Sept. 1975.

Keith M. Carlson, Federal Reserve Bank of St. Louis: adjunct professor, St. Louis University, Jan. 1976.

Leonard A. Carlson, Occidental College: assistant professor of economics, Emory University, Sept. 1975.

Jens P. Christiansen: lecturer in economics, University of California, Santa Cruz, July 1, 1975.

Robert W. Clarke, University of Houston: associate professor of accounting, Rice University, July 1975.

Kenneth W. Clarkson, University of Virginia: professor of economics, Center for Studies in Law and Economics, University of Miami, and University of Miami Law School, Aug. 1975.

Philip R. P. Coelho, Washington State University: visiting associate professor of economics, University of Hawaii, 1975–76.

Anna M. Craig: visiting assistant professor, Ohio State University.

Sheldon Danriger: lecturer, department of economics; research associate, Institute for Research on Poverty, University of Wisconsin-Madison.

Louis De Alessi, George Washington University: visiting professor of economics, Center for Studies in Law and Economics, University of Miami, Aug. 1975.

Rajat Deb, London School of Economics: visiting assistant professor of economics, Southern Methodist University.

Thomas Dernberg: professor, department of economics, American University, Sept. 1, 1975.

Timothy A. Deyak, State University of New York, Binghamtom: assistant professor of economics, Auburn University, Sept. 1975.

Douglas F. Dowd: visiting professor of economics, University of California, Santa Cruz, Jan. 1, 1976.

James A. Dunlevy, Colby College: assistant professor of economics, Auburn University, Sept. 1974.

James C. Dyer, University of Newcastle, New South Wales: assistant professor of accounting, Rice University, July 1975.

Thomas B. Fomby, University of Missouri, Columbia: assistant professor of economics, Southern Methodist University.

Claude Fongemie, University of Connecticut: instructor, economics department, Middlebury College, Aug. 1975.

Murray Foss: senior research associate, National Bureau of Economic Research, May 1975.

Maxwell J. Fry: associate professor of economics, University of Hawaii, Aug. 1, 1975.

Dilip Kumar Ghosh: visiting assistant professor, Ohio State University.

Reuben Gronau: research associate, National Bureau of Economic Research, Aug. 1975.

Kenneth Guentner, University of Pittsburgh: instructor, economics department, Middlebury College, Aug. 1975.

Thomas D. Hall: assistant professor of economics, University of Hawaii, Aug. 1, 1975.

Eric A. Hanushek, U.S. Air Force Academy: associate professor of economics, Yale University, Jan. 1975.

Robert F. Hebert, Clemson University: associate professor of economics, Auburn University, Sept. 1974.

Betty C. Heian: visiting assistant professor of economics, University of Hawaii, 1975–76.

Robert S. Herren: visiting assistant professor of economics, Vanderbilt University, 1975–76.

James D. Hess: assistant professor, department of economics, University of Southern California.

Martha S. Hill: lecturer, department of economics, Eastern Michigan University, 1975–76.

Randall G. Holcombe: visiting assistant professor of economics, Vanderbilt University, 1975–76.

Karen C. Holden: lecturer, department of economics, University of Wisconsin-Madison.

David L. Horner, Wayne State University: senior research economist, Mathematica, Inc., June 1975.

Ethel B. Jones, University of Georgia: professor of economics, Auburn University, Sept. 1975.

Marcus Jones: economist, Market Statistics Division, Federal Reserve Bank of New York, July 21, 1975.

Barbara H. Kehrer, Center for Health Services Research and Development, A.M.A.: senior research economist, Mathematica, Inc., June 1975.

William A. Kelly, Jr., University of North Carolina, Chapel Hill: assistant professor of economics, Rice University, July 1975.

Stuart H. Kerachsky, University of Wisconsin: researcher, Mathematica, Inc., Dec. 1974.

David T. King: economist, Foreign Research Division, Federal Reserve Bank of New York, July 1, 1975.

Nicholas R. Lardy, University of Michigan: assistant professor of economics and East Asian studies, Yale University, July 1975.

Ross La Roe: instructor, department of economics, American University, Sept. 1, 1975.

William J. Lawrence, New York University: researcher, Mathematica, Inc., July 1974.

Chung H. Lee, Miami University: visiting professor of economics, University of Hawaii, 1975–76.

Wassily Leontief, Harvard University: professor, department of economics, New York University, Sept. 1, 1975.

Ben W. Lewis: visiting professor of economics, Virginia Commonwealth University, spring 1975.

James E. Long, Florida State University: assistant professor of economics, Auburn University, Sept. 1974.

Roland N. McKean, University of Virginia: scholar-in-residence, Center for the Study of American Business; adjunct visiting professor of economics, Washington University (St. Louis), spring semester 1976.

Robert J. McMahon: professor of world business, American Graduate School of International Management, Feb. 1976.

William K. MacReynolds: visiting assistant professor, Ohio State University.

James R. Marchand, California State College, Northridge: assistant professor of economics, Virginia Commonwealth University, Aug. 1975.

Karen Margolis: instructor, North Carolina State University, fall 1975.

Donald L. Martin, University of Virginia: research professor of economics, Center for Studies in Law and Economics, University of Miami, Aug. 1975.

Lawrence C. Marsh: assistant professor of economics, University of Notre Dame, fall 1975.

Andrew W. Mason: assistant professor of economics, University of Hawaii, Aug. 1, 1975.

Rebecca Maynard, University of Wisconsin: researcher, Mathematica, Inc., Dec. 1974.

Leon A. Mears: visiting professor, department of economics, University of Wisconsin-Madison.

Oey Astra Meesook: visiting research fellow, National Bureau of Economic Research, Oct. 1975.

Charles C. Metcalf, University of Wisconsin: principal researcher, Mathematica, Inc., June 1975.

John G. Metcalf: assistant professor of economics, Louisiana State University, Aug. 1975.

Laurence Meyer: economist, Money and Finance Division, Federal Reserve Bank of New York, May 29, 1975.

Marc Miles: economist, Balance of Payments Division, Federal Reserve Bank of New York, Sept. 1, 1975.

James L. Mills: assistant professor of economics, American Graduate School of International Management, Sept. 1, 1975.

John A. Miranowski: assistant professor, department of economics, Iowa State University, Apr. 21, 1975.

Hosseine Morewedge, Long Island University: visiting professor, department of economics, University of Southern California, 1974–75.

Warren E. Moskowitz: economist, Balance of Payments Division, Federal Reserve Bank of New York, May 29, 1975.

Michael M. Murphy, University of Chicago: assistant professor of economics, Southern Methodist University.

William F. Murphy: instructor of business administration, Transylvania University.

David J. Nicol, John Carroll University: assistant professor of finance, Cleveland State University, Sept. 1975.

James O'Connor, Pennsylvania State University: visiting assistant professor, University of Iowa, Aug. 1975.

James C. Ohls, Princeton University: senior research economist, Mathematica, Inc., July 1975.

Carol Oliven, ACT: visiting assistant professor, University of Iowa, Aug. 1975.

Randall J. Olsen, University of Chicago: lecturer in economics, Yale University, July 1975.

Jerome Paige: instructor, department of economics, American University, Sept. 1, 1975.

Donald O. Parsons: visiting research fellow, National Bureau of Economic Research, Sept. 1975.

David W. Patterson: instructor of business administration and hotel and restaurant administration, Transylvania University.

Gerald Peabody: visiting associate professor, department of economics, American University, Sept. 1, 1975.

Andrew Policano: assistant professor of economics, University of Iowa, Aug. 1975.

Walter J. Primeaux, University of Mississippi: professor of business administration, University of Illinois, Urbana, fall 1975.

James Ragan: economist, Business Conditions Division, Federal Reserve Bank of New York, Oct. 1975.

Wallace Reed: assistant professor of accounting, American Graduate School of International Management, Sept. 1, 1975.

Harry W. Richardson: professor, economics and urban and regional planning departments, University of Southern California.

Irving Rottenberg: senior research associate, National Bureau of Economic Research, May 1975.

Daniel L. Rubinfeld: research associate, National Bureau of Economic Research, Sept. 1975.

Javier Ruiz-Castillo: visiting assistant professor, University of Iowa, Aug. 1975.

Richard P. Saba, Texas A&M University: assistant professor of economics, Auburn University, Sept. 1974.

T. Paul Schultz, University of Minnesota: professor of economics of population, Yale University, July 1975.

Steven A. Seelig, Federal Reserve Bank of New York: assistant professor of economics, Fordham University, Sept. 1975.

Jennifer G. Sharpley: lecturer, department of economics, University of Wisconsin-Madison.

Russell Sheldon: economist, Business Conditions Division, Federal Reserve Bank of New York, Sept. 1975.

Parthsarathi Shome: assistant professor, department of economics, American University, Sept. 1, 1975.

Allen Sinai, University of Illinois at Chicago Circle: visiting associate professor, Sloan School, Massachusetts Institute of Technology, Sept. 1975.

Charles Sivesind: economist, Business Conditions Division, Federal Reserve Bank of New York, July 1, 1975.

Robert Sleeper: economist, Foreign Research Division, Federal Reserve Bank of New York, Sept. 1, 1975.

Marcellus S. Snow: assistant professor of economics, University of Hawaii, Sept. 1, 1974.

James B. Stewart: assistant professor of economics and director of black studies, University of Notre Dame, fall 1975.

Stephen H. Strand: visiting assistant professor of economics, Vanderbilt University, 1975–76.

Jack P. Suyderhoud, Advisory Committee on Intergovernmental Relations: assistant professor, department of economics, Eastern Michigan University, 1975–76.

Leigh Tesfatsion: instructor, economics department, University of Southern California.

Francisco Thoumi: research associate, National Bureau of Economic Research, Aug. 1975.

John Vahaly, Jr.: visiting assistant professor of economics, Vanderbilt University, 1975–76.

Kenneth Warner: visiting scholar, National Bureau of Economic Research, July 1975.

Kenneth Wolpin: senior research analyst, National Bureau of Economic Research, Sept. 1975.

Steven A. Wood, Claremont Graduate School: assistant professor, department of economics, Eastern Michigan University, 1975–76.

John Woodbury: economist, Balance of Payments Division, Federal Reserve Bank of New York, Aug. 1975.

Brian D. Wright, Harvard University: lecturer in economics, Yale University, July 1975.

Lorene Y. L. Yap, State University of New York, Binghamton: visiting assistant professor of economics, University of Hawaii, 1975–76.

John M. Yinger: lecturer, department of economics; research associate, Institute for Research on Poverty, University of Wisconsin-Madison.

Soogil Young: visiting instructor, Ohio State University.

David Zimmerman, Temple University: researcher, Mathematica, Inc., July 1975.

Burton Zwick: economist, Money and Finance Division, Federal Reserve Bank of New York, June 1975.

Leaves for Special Appointments

Harold H. Barnett, Washington University (St. Louis): fellow, Woodrow Wilson Center, Smithsonian Institute, Jan. 1, 1976.

Nancy Barrett, American University: deputy assistant director, Congressional Budget Office, June 30, 1975.

Sara S. Berry, Indiana University: visiting associate professor, economics and African history, Boston University, Sept. 1975.

Stanley W. Black, Vanderbilt University: research fellow, Institute for International Economic Studies, University of Stockholm, July 1, 1975–July 30, 1976.

Rudolph C. Blitz, Vanderbilt University: Fulbright fellowship, Institut für Industrie- und Verkehrspolitik, Universität Bonn, Germany, 1975–76.

Nicholas Dewitt, Indiana University: manpower planning adviser, National Manpower Board, Federal Ministry of Economic Development and Reconstruction, government of Nigeria, Aug. 1975.

A. Ronald Gallant, North Carolina State University: visiting assistant professor of business, University of Chicago, 1975–76.

Bruce L. Gardner, North Carolina State University: senior staff economist, President's Council of Economic Advisers, Aug. 1, 1975–July 31, 1976.

R. Jeffery Green, Indiana University: senior staff economist, President's Council of Economic Advisers, Jan. 1975.

Edmond Q. Haggart, Kansas State University: Staff of Joint Congressional Committee on the Budget, June 1975.

George Iden, American University: senior analyst, Congressional Budget Office, May 15, 1975.

James R. Jeffers, University of Iowa: USAID-Korea, May 1975.

Hyman Joseph, University of Iowa: Indiana University, Sept. 1975.

Kwan S. Kim, University of Notre Dame: Rockefeller visiting senior lecturer, University of Dar Es Salaam, 1975–76.

John R. Moroney, Tulane University: visiting professor of economics, Massachusetts Institute of Technology, 1975–76.

Seiji Naya, University of Hawaii: Rockefeller award, visiting professor of economics, Thammasat University, Bangkok, 1975–76.

Edwin G. Olson, Kansas State University: temporary consultant to the Washington State Department of Revenue, Sept. 1975.

Saul Pleeter, Indiana University: economist, U.S. Department of Labor, Washington, D. C., Sept. 1975.

Gordon C. Rausser, Iowa State University: visiting professor, Harvard University, Sept. 1, 1975.

Dominick Salvatore, Fordham University: Fulbright research/lecturer, Italy, 1975–76.

Gian S. Sahota, Vanderbilt University: visiting professor of economics, Fundação Instituto de Pésquisas Economicas (FIPE), University of São Paulo, Brazil, fall semester 1975.

Edward Shapiro, University of Toledo: visiting professor of economics, East Anglia University, England, Sept.–Dec. 1975.

John J. Siegfried, Vanderbilt University: economist, Federal Trade Commission, spring semester 1976.

Gary H. Stern: visiting assistant professor, Washington University (St. Louis), Sept. 1975–June 1976.

Gary M. Walton, Indiana University: visiting professor, department of economics, University of California, Berkeley, Aug. 1975.

James Weaver, American University: faculty, Development Studies Program, Agency for International Development, May 1, 1975.

Kenneth J. White, Rice University: visiting assistant professor, University of British Columbia, 1975–76.

Resignations

Ruben D. Almonacid, Vanderbilt University, May 15, 1975.

Charles W. Bischoff, Yale University: International Business Machines, July 1975.

Thomas F. Dernburg, Oberlin College: American University, Sept. 1, 1975.

Allan C. Deserpa, Louisiana State University, Dec. 1974.

Peter T. Gottschalk, University of California, Santa Cruz, July 1, 1975.

H. Robert Heller, University of Hawaii, June 31, 1975.

Treena K. Levins, Iowa State University, Mar. 14, 1975.

Edwin J. Longfellow, Iowa State University, May 31, 1975.

G. S. Maddala, University of Rochester: University of Florida, Sept. 1, 1975.

Carl W. O'Connor, Iowa State University: Oregon State University, July 18, 1975.

Roy J. Ruffin, University of Iowa: Carlton University, Aug. 1975.

Kenneth R. Smith, University of Wisconsin-Madison: Northwestern University, June 1975.

Frederick T. Sparrow, Johns Hopkins University, Feb. 1, 1975.

Ross M. Starr, Yale University: University of California, Davis, Jan. 1975.

Joseph A. Swanson, University of Iowa: Northwestern University, Aug. 1975.

Darwin Wassink, University of Iowa: Development Assistance Corp., June 1975.

Charles K. Wilber, American University: University of Notre Dame, Sept. 1, 1975.

Michael Zubkoff, Dartmouth Medical School and Dartmouth University, Sept. 1975.

Miscellaneous

Rawle Farley: appointed member, State University of New York University Commission on Purposes and Priorities.

◆

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3×5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

SEVENTY-SECOND LIST OF DOCTORAL DISSERTATIONS IN POLITICAL ECONOMY IN AMERICAN UNIVERSITIES AND COLLEGES

The present list specifies doctoral degrees conferred during the academic year terminating June 1975. Abstracts will no longer be printed, as they are published by University Microfilms, Ann Arbor, Michigan.

General Economics; including Economic Theory, History of Thought, Methodology, Economic History, and Economic Systems

BURTON A. ABRAMS, Ph.D. Ohio State 1974. An economic theory of lobbying: A case study of the *U.S.* banking industry.

FRANCIS H. ACKERMAN, Ph.D. Harvard 1975. Riots, populism, and nonindustrial labor: A comparative study of the political economy of the urban crowd.

SYED M. AHSAN, Ph.D. McMaster 1974. Taxation and behavior under uncertainty.

JUDITH A. ALEXANDER, Ph.D. Simon Fraser 1974. Some aspects of consumer related behavior when goods are interrelated.

ROBERT C. ALLEN, Ph.D. Harvard 1975. International competition and the growth of the British iron and steel industry: 1880–1913.

RALPH V. ANDERSON, Ph.D. North Carolina 1974. Labor utilization and productivity, diversification and self-sufficiency, southern plantations, 1800–1840.

ROBERT B. ARCHIBALD, Ph.D. Purdue 1974. Uncertainty, atomistic competition, and excess supply of labor.

WILLIAM M. BAILEY, Ph.D. Maryland 1973. The price revolution, population growth, and agricultural change in Tudor England.

WILLIAM G. BAKER, Ph.D. Nebraska 1975. A business history of Security Mutual Life Insurance Company.

RAYMOND BALLARD, Ph.D. Texas A&M 1974. The demand for nonmarket time.

GERRIT BILKES, Ph.D. State University of New York (Stony Brook) 1974. Macrotheoretic implications of the lot size model for inventories.

CRAIG BOLTON, Ph.D. Texas A&M 1974. The British historical school in political economy: Heterodox meta-economics in the Victorian age.

RHEAD S. BOWMAN, Ph.D. Utah 1975. Jevons on theory and social change.

JAMES W. BOYD, Ph.D. California (Santa Barbara) 1974. Consumer bid transactions with risk.

GERARD F. X. BROWN, Ph.D. Georgetown 1975. Indeterminism and the diffusion index.

JOHN B. BRYANT, Ph.D. Carnegie-Mellon 1975. Inventory behavior.

GERARD BUTTERS, Ph.D. Chicago 1975. Equilibrium price distributions and the economics of information.

JOSEPH P. CAIN, Ph.D. Southern Methodist 1974. An economic analysis of the determination of the quantity and quality of children by the household.

XAVIER CALSAMIGLIA, Ph.D. Minnesota 1975. On the possibility of informational decentralization in nonconvex environments.

JOHN S. COOK, Ph.D. Purdue 1974. Monopolistic solutions in general equilibrium theory.

RICHARD T. CURTIN, Ph.D. Michigan 1975. Perceptions of distributional equity: Their economic bases and consequences.

ANDREW J. DANE, Ph.D. Oklahoma. The industrial sectors of East Germany and West Germany.

JAMES A. DOILNEY, Ph.D. Maryland 1974. Equity, efficiency, and intertemporal resource allocation decisions.

EVAN J. DOUGLAS, Ph.D. Simon Fraser 1974. Edgeworth models of the firm.

JOHN T. DOYLE, Ph.D. Illinois 1975. Cooperation and competition in communal organization.

JAMES T. DYAL, Ph.D. Illinois 1975. Efficiency of investment in graduate education.

JOHN L. EATWELL, Ph.D. Harvard 1975. Scarce and produced commodities: An examination of some fundamentals in the theory of value, with particular reference to the works of Ricardo and Walras.

JOHN C. ECKALBAR, Ph.D. Colorado 1975. Imperfect market information in partial and general disequilibrium.

BENJAMIN EDEN, Ph.D. Chicago 1975. Aspects of uncertainty in simple monetary models.

EVERETT M. EHRLICH, Ph.D. Michigan 1975. The distribution and effects of exogenous disruptions of life cycle plans among labor force participants, 1967–1972.

JOHN B. ELSTROTT, Ph.D. Colorado 1975. Philosophical foundations of liberalism.

RICHARD W. ENGLAND, Ph.D. Michigan 1974. Capital, economic growth, and environmental pollution.

GEORGE M. FEIGER, Ph.D. Harvard 1975. Anticipations and information in speculative markets.

ALEXANDER J. FIELD, Ph.D. California (Berkeley) 1975. Educational reform and manufacturing development in mid-nineteenth century Massachusetts.

CHARLES C. FISCHER, Ph.D. Washington State 1975. Limitations of the equilibrium method in economics.

ROBERT E. FORSYTHE, JR., Ph.D. Carnegie-Mellon 1975. Essays on the theory of incomplete markets.

CHARLES G. GEISS, Ph.D. North Carolina 1975. Consistent price indices.

LEONARD F. GIESECKE, Ph.D. Texas (Austin) 1975.

History of American economic policy in the Philippines during the American colonial period: 1900–1935.

EILEEN C. GRAM, Ph.D. Wisconsin (Madison) 1975. How to raise women's wage—an evaluation of a women's liberation proposal within the context of a general equilibrium model.

SANFORD GROSSMAN, Ph.D. Chicago 1975. Essays on rational expectations, the informational role of futures markets, and equilibrium Bayesian experimentation.

CARL M. GUELZO, Ph.D. Maryland 1974. An institutionalist reconstruction of the theory of the firm.

MILTON Y. HARRIS, Ph.D. Chicago 1974. Optimal planning under transaction costs and general equilibrium.

HIROAKI HAYAKAWA, Ph.D. Michigan 1974. Three essays on consumer choice.

RONALD A. HEINER, Ph.D. California (Los Angeles) 1975. The exchange of collective goods and the existence of generalized competitive equilibrium.

WILLIAM L. HELKIE, Ph.D. Purdue 1974. Studies in applied stochastic microeconomics.

NEAL O. HIGGINS, Ph.D. Nebraska 1974. The early pension plans of the Baltimore and Ohio and the Pennsylvania Railroads, 1880–1937.

JOSEPH P. HUGHES, Ph.D. North Carolina 1974. Two studies of incomplete optimization in economic theory.

TATSURO ICHIISHI, Ph.D. California (Berkeley) 1975. Some generic properties of smooth economies.

FREDERICK S. INABA, Ph.D. California (Berkeley) 1975. Pure exchange equilibrium of a dynamic economy with stochastic endowments.

CHARLES INGENE, Ph.D. Brown 1975. An integration of location and central places theories, given industrial interaction.

RICHARD IPPOLITO, Ph.D. Chicago 1974. The division of labor in the firm.

JAMES S. JORDAN, Ph.D. Northwestern 1975. Temporary competitive equilibrium and the existence of self-fulfilling expectations.

AMOZ KATS, Ph.D. Minnesota 1974. Some models of sequential consumption decisions under uncertainty.

JEAN-JACQUES M. LAFFONT, Ph.D. Harvard 1975. Essays in economics of uncertainty: Information acquisition and instrument dependent randomness.

CHARLES E. LAMBERTON, Ph.D. Iowa State 1975. Localized technical progress in a dynamic theory of the firm.

DENNIS R. LAVIGNE, Ph.D. Illinois 1975. The steady-state growth of the public sector.

JOHN C. LEFGREN, Ph.D. Utah 1975. Banking in the early industrialization of Finland, 1860–1914.

CHARLES LIEBERMAN, Ph.D. Pennsylvania 1974. An investigation of the short-run effects of capital gains on household consumption and saving.

IAN McDONALD, Ph.D. Simon Fraser 1974. A Keynesian theory of the rate of profit.

GORDON C. McMEEKIN, Ph.D. Wayne State 1974. An empirical test of alternative estimation techniques for the consensus and coalition approaches to the committee decision problem.

JAMES G. MACKINNON, Ph.D. Princeton 1975. Economic general equilibrium models: Essays on computation, existence, and estimation.

MARCO MARTINS, Ph.D. Chicago 1975. The private and the social optimum quantity of public debt in a pure consumption-loans model.

GERALD L. MILLER, Ph.D. Notre Dame 1975. Keynesian economics as a "Scientific Revolution."

JOSEPH MINARIK, Ph.D. Yale 1974. A microanalysis of the size distribution of income.

TAPAN MITRA, Ph.D. Rochester 1975. Efficient capital accumulation in infinite horizon models.

JOEL MOKYR, Ph.D. Yale 1974. Industrial growth and stagnation in the low countries, 1795–1850.

SCOTT J. MOSS, Ph.D. New School 1975. On the logic of capitalist accumulation.

EDWARD J. MULHOLLAND, Ph.D. Boston College 1974. An economic analysis of the political behavior of the British Labor Party.

PAUL G. MUNYON, Ph.D. Harvard 1975. A reassessment of New England agriculture in the last thirty years of the nineteenth century: New Hampshire, a case study.

ALLEN R. NEWMAN, Ph.D. North Carolina 1975. An analysis of German internal migration, 1880–1900.

ELI M. NOAM, Ph.D. Harvard 1975. The criminal justice system: An economic analysis of benefits and interrelations.

JAMES F. O'CONNOR, Ph.D. Minnesota 1975. Multiperiod production under uncertainty.

GERALD P. O'DRISCOLL, JR., Ph.D. California (Los Angeles) 1974. Economics as a coordination problem: The contributions of Friedrich A. Hayek.

MARVIN M. OTT, Ph.D. California (Los Angeles) 1975. The consumption-investment decision under uncertainty.

JAMES V. PINTO, Ph.D. Oklahoma. Background and development of location theory: An essay in the history of economic thought.

RICHARD W. T. POMFRET, Ph.D. Simon Fraser 1974. The introduction of the mechanical reaper in Canada 1850–70: A case study in the diffusion of embodied technical change.

ROBERT C. POSATKO, Ph.D. Pennsylvania State 1975. Lifetime parent-to-offspring wealth transfers and utility interdependence.

PATRICIA QUICK, Ph.D. Harvard 1975. Education and industrialization: Elementary education in nineteenth century England and Wales.

RAMA RAMACHANDRAN, Ph.D. Brown 1975. Long-run production function and endogenous technical progress—a neoclassical approach.

WILLIAM S. REECE, Ph.D. Washington (St. Louis) 1975. A disequilibrium model of wage dynamics.

THOMAS P. REINWALD, Ph.D. Illinois 1973. The development and methodology of imperfect and monopolistic competition.

GEORGE RHODES, Ph.D. Texas A&M 1974. An analysis of income, spending, and labor supply in a token economy.

DAVID L. ROBERTS, Ph.D. Duke 1975. Keynes and the system of the Keynesians.

SERGIO ROCA, Ph.D. Rutgers 1975. Economic structure and ideology in socialist Cuba.

THOMAS ROMER, Ph.D. Yale 1974. Social choice criteria and the properties of a simple income tax.

TERRY L. RUSH, Ph.D. Oklahoma. The Keynesian-monetarist debate: An analysis and synthesis.

TERRANCE C. I. RYAN, Ph.D. Massachusetts Institute of Technology 1975. The economics of trading in slaves.

RICHARD SABA, Ph.D. Texas A&M 1974. Information cost and the theory of discrimination.

ANNA M. SACHKO, Ph.D. Columbia 1975. An analysis of the demand for life insurance.

ERNESTO F. SANZ, Ph.D. Boston College 1975. Polity primacy and microeconomic structures in the economic development of Taisho Japan.

MARK D. SCHMITZ, Ph.D. North Carolina 1974. Economic analysis of antebellum sugar plantations in Louisiana.

JOHN J. SEATER, Ph.D. Brown 1975. A unified model of consumption, labor supply, and job search.

GORDON H. SELLON, JR., Ph.D. Michigan 1974. A want-hierarchy approach to the theory of consumer behavior.

MARVIN SHAFFER, Ph.D. British Columbia 1974. The role of competition in macro models.

IRWIN A. SHAPIRO, Ph.D. Clark 1974. A test of the effect of windfall receipts on consumption.

STEVEN M. SLUTSKY, Ph.D. Yale 1975. Majority voting and the allocation of public goods.

JON C. SONSTELIE, Ph.D. Northwestern 1975. Public goods and property values.

DAVID H. SWINTON, Ph.D. Harvard 1975. The logic of economic discrimination in noncompetitive labor markets.

MO-YIN TAM, Ph.D. State University of New York (Stony Brook) 1974. On the role of "information flows" in the theory of optimal policies.

ARVIND VIRMANI, Ph.D. Harvard 1975. A dynamic theory of the firm: Expectations, investment, and growth.

MICHAEL L. VISSCHER, Ph.D. Virginia 1975. The value of consumers' waiting time in the supply of goods.

MARK S. WALDMAN, Ph.D. Florida 1974. Galbraith's paradigm: A case study in scientific revolution.

PETER G. WARR, Ph.D. Stanford 1974. The theory of shadow pricing.

FRANK WESTHOFF, Ph.D. Yale 1974. The theory of local public goods.

HUGH R. WILLS, Ph.D. California (Berkeley) 1975. Vintage capital and the theory of the firm.

RICHARD J. WILTGEN, Ph.D. Illinois 1974. Marxism and population: A reappraisal.

DANIEL WISECARVER, Ph.D. Chicago 1974. Three essays in the theory of applied welfare economics.

GLENN A. WITHERS, Ph.D. Harvard 1975. The political economy of the volunteer military.

GARY W. YOHE, Ph.D. Yale 1975. A comparison of price controls and quantity controls under uncertainty.

JEFFREY T. YOUNG, Ph.D. Colorado 1975. The rehabilitation of the classical theory of value in historical perspective.

Economic Growth and Development; including Economic Planning Theory and Policy, Economic Fluctuations and Forecasting

DOUGLAS ADKINS, Ph.D. California (Berkeley) 1975. Economic planning and the specialized degree output of higher education in the United States.

ABUBAKR BIN AHMAD, Ph.D. Indiana 1974. Development strategies for Ghana: A determination of alternative policies for 1980.

FAKHRUDDIN AHMED, Ph.D. Princeton 1975. Migration and employment in a multisector model: An application to Bangladesh.

LOUKAS I. ANANIKAS, Ph.D. Michigan State 1975. Potential livestock production adjustments on family farms in central Macedonia, Greece.

YIADOM ATTAKONDADU, Ph.D. Michigan State 1974. Economic optima in resource allocation for smallholder subsistence farming in Ghana.

CARLOS A. BAANANTE, Ph.D. North Carolina State 1974. Andean group economic integration: The case of the nitrogenous fertilizer industry.

LLOYD BARON, Ph.D. McGill 1975. The water supply constraint: An evaluation of irrigation projects and their role in the development of Afghanistan.

CIHAN M. BELEN, Ph.D. Connecticut 1975. The role of the state economic enterprises in the development of Turkey.

JEFFREY I. BERNSTEIN, Ph.D. Western Ontario 1975. Essays on the dynamic theory of optimal policy for an open economy.

ASHOK BHARGAVA, Ph.D. Wisconsin (Madison) 1975. The effect of a rise in the rate of interest on corporate behavior: A case study of India.

STEVEN Y. F. BONAWU, Ph.D. Nebraska 1974. The financial sector and economic development: The Liberian case.

FRANCOIS BOURGUIGNON, Ph.D. Western Ontario 1975. Two essays in economic growth theory.

IVY BRODER, Ph.D. State University of New York (Stony Brook) 1974. Statistical analyses of cyclical indicators.

EMIN CARIKCI, Ph.D. New School 1975. Workers' migration to the European Economic Community (EEC) countries and Turkish economic development.

Daniel S. Christiansen, Ph.D. Stanford 1975. Some aspects of the theory of short-run equilibrium.

W. Edmund Clark, Ph.D. Harvard 1974. Socialist development and public investment in Tanzania: 1964–1973.

Harry M. Cleaver, Jr., Ph.D. Stanford 1975. The origins of the Green Revolution.

Arthur L. Coffing, Ph.D. Iowa State 1974. PL-480 imports, the disincentive effect, and implications for development in Turkey.

William E. Conrad, Jr., Ph.D. Massachusetts Institute of Technology 1975. Uncertainty and optimal stabilization policy.

Roy E. J. Culpepper, Ph.D. Toronto 1975. Import substitution, self-reliance, and the choice of techniques: A study of the Indian fertilizer industry.

Gunars Dambe, Ph.D. Iowa State 1974. Planning for more labor intensive and more productive agriculture in Columbia.

Asim K. Dasgupta, Ph.D. Massachusetts Institute of Technology 1975. Two essays on income distribution in a developing economy.

Nicholas J. DeGrazia, Ph.D. Michigan State 1974. Stock markets and development: A case study of Panama.

Lawrence E. Demilner, Ph.D. Southern California 1975. The formation of price expectations and their behavior in wage change and interest rate equations.

Evelyn Hazel Denton, Ph.D. Harvard 1975. Economic determinants of fertility in Jamaica.

Bhupendra M. Desai, Ph.D. Cornell 1974. Relationship of consumption and production in changing agriculture: A study in Surat District, India.

Carl A. Futia, Ph.D. California (Berkeley) 1975. Information costs and boundedly rational behavior: A comparative equilibrium.

Kenneth D. Garbade, Ph.D. Princeton 1975. Discretionary control of aggregate economic activity.

Arthur Gibb, Jr., Ph.D. Michigan 1974. Agricultural modernization, nonfarm employment, and low-level urbanization.

Nicholas P. Glytsos, Ph.D. Syracuse 1974. Dynamic price changes, wages, and unemployment in the urban sector of the less developed countries: An intertemporal cross-sectional econometric model.

Robert E. Gray, Ph.D. Michigan State 1975. Agricultural export potentials and balance-of-payments aspects of the Nigerian economy.

Jean Guertin, D.B.A. Harvard 1974. An evaluation of forecasts by financial analysts.

Lawrence H. Hadley, Ph.D. Connecticut 1975. An international comparative analysis of educational strategies in under-developed countries incorporating rates of return to education.

Khalil Ahmed Hamdani, Ph.D. Georgetown 1975. Risk, social structure, and economic behavior in the peasant economy.

Barry M. Herman, Ph.D. Michigan 1974. Strategies of foreign manufacturing investment in poor countries: A general theory and an application to oil refining in East Africa.

Shigemochi Hirashima, Ph.D. Cornell 1974. Interaction between institutions and technology in developing agriculture: A case study of the disparity problems in Pakistan agriculture.

DAVID P. VOGT, Ph.D. Syracuse 1974. An interregional analysis of the empirical importance of factor intensity reversals.

WALTER H. VOGT, Ph.D. Syracuse 1974. Income distribution of fiscal centralization: A comparative analysis of the effects in ten *U.S.* central cities.

THOMAS J. WALSH, Ph.D. California (Berkeley) 1975. An exploration of the effects of sponsored research on higher education.

IRWIN J. WARGON, Ph.D. California (Los Angeles) 1974. An economic analysis of blood outdating in the United States.

ANDREW T. WILLIAMS, Ph.D. Stanford 1975. An economic analysis and evaluation of California's probation subsidy program: A case study of a performance grant-in-aid program.

RONALD L. WILLIAMS, Ph.D. California (Santa Barbara) 1974. Outcome-based measurements of medical care output: The case of maternal and infant health.

ROBERT H. WILSON, Ph.D. Yale 1975. The methodological defects of "urban dynamics" and their implications for the study of social systems.

JOHN M. YINGER, Ph.D. Princeton 1975. Three essays on the economics of discrimination in housing.

JAMES A. ZINGALI, Ph.D. Florida State 1975. A theoretical and empirical analysis of the relationship between city size and income.

ANNOUNCEMENT

NOTICE TO ALL GRADUATE DEPARTMENTS

The December 1976 issue of the *Review* will carry the seventy-third list of doctoral dissertations in political economy in American universities and colleges. The list will specify doctoral degrees conferred during the academic year terminating June 1976. This announcement is an invitation to send us information for the preparation of the list. This announcement supersedes and replaces a letter which was sent annually from the managing editor's office.

The *Review* will publish in its December 1976 issue the names of those who will have been awarded the doctoral degree since June 1975 and the titles of their dissertations. Dissertation abstracts will no longer be published, as these are published elsewhere.

By June 30, please send us this information on 3×5 cards, conforming to the style shown below, one card for each individual. Please indicate by a classification number in the right-hand corner the field in which the thesis should be classified. The classification system is that used by the *Journal of Economic Literature* and printed in every issue.

JEL Classification No. ________

Name: LAST NAME IN CAPS: First Name, Initial

Institution Granting Degree: ________

Degree Conferred (Ph.D. or D.B.A.) ________ Year ________

Dissertation Title: ________

When degrees in economics are awarded under different names, such as Business Administration, Public Administration, or Industrial Relations, candidates in these fields whose training has been ***primarily in economics*** should be included.

All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

Join the American Economic Association

Membership includes:

- a subscription to both *The American Economic Review* (quarterly) plus May, *Papers and Proceedings* and the *Journal of Economic Literature* (quarterly)
- annual ballots and nomination forms for elected officers of the Association
- preregistration material and announcement of the annual meeting of the Allied Social Science Associations
- announcements of special interest to members, such as the life insurance program started in 1973; new book offerings, etc.

1976 ANNUAL MEMBERSHIP RATES

Class 1	Regular member with rank of assistant professor or lower or annual income of $12,000 or less	$25.00
Class 2	Regular member with rank of associate professor or annual income of $12,000-$20,000	$30.00
Class 3	Regular member with rank of full professor or annual income above $20,000	$35.00
Class 4	Junior member (registered students; certification must be submitted yearly) Student status must be certified by your major professor or school registrar; please use the space provided below	$12.50
	Members in classes listed above living in a foreign country should include one of the following amounts for postage; $2.10 P.U.A.S. countries or $2.50/all other countries and Canada.	
Class 5	Family member (second membership without publications; two or more living at same address)	$ 5.00
	Dues payable in U. S. currency only.	

(Under the terms of a resolution passed at the annual meeting of members of the American Economic Association on Dec. 29, 1973, $20.00 of the annual membership dues is considered as payment for the AER and JEL; the remainder is considered a contribution to exempt functions of the Association.)

What Samuelson knows about economics...could fill ten editions, and does!

Professionals do not reach the zenith of their field by resting on their laurels. Neither does a textbook. That's why Paul A. Samuelson's ECONOMICS, now in its Tenth Edition, has continued to grow, reflecting the author's continued growth.

Concentrating on the last quarter of the twentieth century, its problems and their implications, the Tenth Edition is filled with new insights on energy. Professor Samuelson has personally scrutinized the entire book, particularly the material on OPEC countries; ecology; shortages; inflation and recession; and the Federal Reserve. And the major statistical tables, charts, and textual facts were expertly updated by Peter Temin, Economic Historian and professor at MIT.

Samuelson is a respected book because it *has* changed with the times. For example:

- The emphasis of the microeconomic chapter on agriculture has been shifted from farm price supports to the new world-wide scare of population pressure, possible adverse climatic change, and apprehensions that the terms of trade may shift in coming decades in favor of Iowa and prime farm regions and against industrial and developing nations.
- The revised chapters on macroeconomics now consider the fact that the world-wide recession of 1973-75, the worst in the post World War II age of Keynes, has been primarily characterized by "stagflation", or stagnation with inflation. The monetarist debate is also summarized.
- Part Six's policy formulation grapples with the new facts concerning energy scarcity and OPEC cartel oil pricing.
- This edition concentrates on problems concerning the quality of life, sex and racial discrimination, and comparative economic systems in respect to their ideology on equality and incentives. The worsening Phillips curve and the rate of deteriorating national unemployment in the world's affluent countries are also treated.

Prices subject to change without notice.

ECONOMICS TENTH EDITION

Paul A. Samuelson,

MACROECONOMICS: THE THEORY OF INCOME, EMPLOYMENT, AND THE PRICE LEVEL

Michael R. Darby, University of California, Los Angeles, 1976, 480 pages (tent.), $12.95

Reflecting developments in macroeconomic theory over the past fifteen years, this text presents a new, teachable synthesis of modern macroeconomics within a dynamic framework. Its central theme is that macroeconomic shocks begin processes of adjustment toward long-run growth equilibriums, processes which may take several years.

MACROECONOMICS, Fifth Edition

Thomas F. Denburg, American University, and **Duncan M. McDougall,** University of Kansas and Queens University, 1976, 528 pages (tent.), $12.50 (tent.)

Completely revised and updated, the Fifth Edition of this popular intermediate macroeconomics text takes a contemporary look at inflationary-recession and problems of policy mix. It also comprehensively discusses international policy problems and the policy choices available to economies under new international arrangements.

BETTER ECONOMICS BOOKS

SOLUTIONS: A NEW ECONOMIC HISTORY OF AMERICA

Gerarld Gunderson, North Carolina State University, 1976, 640 pages (tent.), $11.95 (tent.)

This comprehensive, up-to-date text excellently applies economic analysis to help readers understand economic behavior—past and present. The broad approach includes the entire span of American history, starting with the economies of the pre-Columbian Indians and ending with modern economic developments after World War II.

AN INTRODUCTION TO MODERN THEORIES OF ECONOMIC GROWTH

Hywel G. Jones, Oxford University, 1976, 304 pages (tent.), $14.95 (tent.)

Systematic and precise, this intermediate text surveys the principal theories and models of economic growth. Emphasizing economic rather than mathematical problems, the text shows how these theories are linked with other areas of economics and discusses why strong controversies have occurred.

MONEY AND BANKING

Dudley G. Luckett, Iowa State University, 1976, 544 pages (tent.), $13.95 (tent.)

Covering material previously available only in professional journals, this text uses regression analysis to treat economic theory and describe economic institutions. Factual material is arranged in a cause-and-effect framework, permitting economists to test theoretical hypotheses against factual evidence.

COLLEGE DIVISION **McGRAW-HILL BOOK COMPANY** 1221 Avenue of the Americas, New York, New York 10020

PUBLIC FINANCE IN THEORY AND PRACTICE, Second Editon

Richard A. Musgrave, Harvard University, and **Peggy B. Musgrave,** Northeastern University, 1976, 768 pages (tent.), $14.50

The Second Edition of this widely acclaimed text combines sound economic analysis with rich empirical and institutional material. Discussing such major topcis as the proper size of the public sector, issues of income redistribution, welfare and social security, among others, the text examines the economics of fiscal policies in conjunction with politcal and social forces surrounding them.

THE ECONOMICS OF POVERTY

Richard Perlman, University of Wisconsin, 1976, 224 pages (tent.), $4.95 (tent.) soft

Presenting a balanced, objective view of the economics of poverty in the United States, this text closely relates poverty to economic institutions within the framework of background, causes, and corrective measures. It uses elementary data analysis to explain and exemplify the theoretical and conceptual issues examined.

ECONOMETRIC MODELS AND ECONOMIC FORECASTS

Robert S. Pindyck, Massachusetts Institute of Technology, and **Daniel L. Rubinfeld,** University of Michigan, 1976, 704 pages (tent.), $14.95 (tent.)

Introducing the science and art of building models, the authors help readers determine the type of model to build, test the model statistically, and apply it to practical forecasting and analytic problems.

MAKE BETTER ECONOMISTS!

THE NEW INDUSTRIAL ORDER: CONCENTRATION, REGULATION, AND PUBLIC POLICY

Samuel R. Reid, University of New Hampshire, 1976, 256 pages (tent.), $8.95 (tent.)

Focusing on microeconomic developments within industrial and financial organization, Professor Reid examines economic concentration as a comprehensive phenomenon, treating both international and national dimensions. Concerned with issues, he examines a variety of empirical studies, and makes public policy suggestions covering federal, state, and local levels of action.

REGULATION: A CASE APPROACH

Leonard W. Weiss, University of Wisconsin, Madison, and **Allyn Strickland,** University of Wisconsin, 1976, 224 pages (tent.), $5.95, soft cover

This is the first junior/senior level case book in regulation. Broad in scope, its case studies include the constitutional and economic basis for control, regulatory rate-making (and marginal cost pricing), regulation in transportation, and others. All case studies are carefully excerpted and prefaced by an introduction for each major set of cases.

New Textbooks from
ACADEMIC PRESS

**ECONOMICS:
PRIVATE AND PUBLIC CHOICE**

JAMES D. GWARTNEY
Florida State University

An important new principles textbook that focuses on giving the student an understanding of the economic way of thinking. Professor Gwartney applies economic analysis to modern economic issues and supports these applications with timely examples, real world supportive data, and presentations of both the strengths and weaknesses of policy alternatives.

In addition to the traditional market analysis, Gwartney thoroughly treats collective decision-making, and compares and contrasts the two processes.

With supplementary materials:
COURSEBOOK—A student guide with self-tests and readings.
TEST BANK—A large selection of class-tested multiple choice questions.

Ready February, 1976   about 700 pages

Available now:

**MONEY AND INFLATION:
A MONETARIST APPROACH**

J. HUSTON McCULLOCH
Boston College

A new supplementary textbook examining the theoretical and practical aspects of the monetary theory of inflation from an unabashedly monetarist point of view.

121 pages, $3.95

The ECONOMICS INSTITUTE

SPECIAL PROPAEDEUTIC TRAINING AND ORIENTATION PROGRAM FOR

INTERNATIONAL Graduate Students in ECONOMICS and RELATED FIELDS

UNIVERSITY OF COLORADO, JANUARY 19 - AUGUST 18, 1976

With six consecutive sessions beginning January 19, February 23, March 29, May 3, June 7 and July 12, 1976.

The Institute is specially designed for students from other countries who are planning to undertake graduate studies at universities in the United States in economics and related fields, including business and agricultural economics. An intensive and specialized *English* instructional program is progressively substituted by an expanding component of preparatory course offerings in *mathematics, statistics* and *economic theory,* and lectures and research seminars on special field topics including agriculture, business and development. The program also includes field trips and social recreational activities designed to acquaint the participants with campus and community life in the United States.

Admissions to the sessions beginning in January, February, March, and May, are restricted to students needing further intensive training in English; those who would score in excess of 500 on the TOEFL at the point of registration should apply for the later (summer) sessions.

Universities and sponsoring agencies are invited to utilize the Institute's Credentials Evaluation Service and its Spring and Summer testing and training programs in their evaluation of candidates for graduate program admissions and related financial support.

Further information and application materials may be obtained from the DIRECTOR, ECONOMICS INSTITUTE, UNIVERSITY OF COLORADO, BOULDER, COLORADO 80302, U.S.A.

Program sponsored by the

American Economic Association

in cooperation with

The American Assembly of Collegiate Schools of Business

Good business from Wiley/Hamilton.

MACROECONOMICS:

Measurement, Theory, and Policy
By Michael C. Lovell,
Wesleyan University

This is an outstanding text for intermediate and upper-level courses in macroeconomics. Lovell stresses modern theoretical advances in analyzing unemployment, inflation, balance of payments, disequilibrium, business cycles, growth.

Schematic flowcharts show students how the equations which constitute the building blocks of a sequence of models fit together. Each chapter ends with a list of key concepts, exercises, and problems.

1975 $14.95

ECONOMICS AND SOCIETY

By Leonard W. Weiss,
University of Wisconsin, Madison

Some economics books stand out. Among these few, Weiss is simply outstanding.

ECONOMICS AND SOCIETY builds its analysis around supply and demand, and aggregate supply and demand. But the theory remains as straightforward as possible—never presented for its own sake. Rather, concepts are applied to such policy issues as monopoly, discrimination, labor market, balance of payments, and public goods. While kept elementary, every concept is developed in the context of realistic, practical experience...to give your students the major elements of economics in a meaningful, realistic setting.

1975 $10.95

MACROECONOMICS:

Money, Prices, and Income
By Dudley W. Johnson,
University of Washington

This book presents an integrated approach to macroeconomics, that is, it covers the traditional subject matter, as well as the economics of money and banking, and international monetary economics. It also provides an exhaustive analysis of monetarism versus fiscalism.

November 1976 $11.95 (tent.)

Forthcoming:

MICROECONOMICS: Theory and Applications

By Robert Y. Awh,
Mississippi State University

Awh offers a balanced, comprehensive coverage of up-to-date intermediate microeconomics, combining a solid treatment of theory with real-world applications. 1976

MACROECONOMICS, Third Edition

By John Lindauer,
Murray State University, Kentucky

This is a thorough, straightforward, and graphic treatment of macroeconomics. This edition has been revised to provide an up-to-date analysis of the state of the art.

February 1976

INTRODUCTION TO ECONOMICS: an issues approach

By Chris Rhoden, Solano College

Pedagogically sound, extremely readable: Rhoden's INTRODUCTION TO ECONOMICS features objectives, summaries, glossaries, and discussion questions for each chapter—as well as related readings drawn from Business Week, Wall Street Journal, etc. Also included: brain teasers (projects for student research).

This introduction to basic concepts and contemporary issues is perfect for the one-term basic economics course. Available with an Instructor's Manual and a Student Study Guide.

February 1976 $9.95 (tent.)

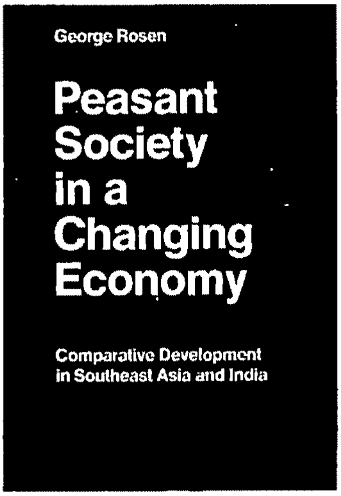
PEASANT SOCIETY IN A CHANGING ECONOMY

Comparative Development in Southeast Asia and India

GEORGE ROSEN



George Rosen

Peasant Society in a Changing Economy

Comparative Development in Southeast Asia and India

Stressing the possibility of revolution in the Philippines, Indonesia, and Thailand — unless significant change in their governments occurs — George Rosen suggests ways to avoid widespread human misery and social and political instability in Southeast Asia. In this interdisciplinary study, he relates the process of social and political change to that of economic development and compares the experiences of these three countries with those of India. ". . . embodies wide-ranging and imaginative scholarship on a series of very significant problems." — Milton J. Esman, Center for International Studies at Cornell University. 269 pages. **$8.95**

Benjamin J. Taylor and Fred Witney's LABOR RELATIONS

Revised to provide an even more effective basic text or supplement for courses in labor law, industrial relations, and government and labor. Suitable for the undergraduate liberal arts student, and the business or law student.

Flexible in format. Chronicles the dynamic history of labor relations, with focus on the environment shaping the legal structure of labor relations. To maintain student interest, the authors analyze the environment of labor relations legislation by tracing the etiology of the main issues — from their origins down through the present day.

About half the book examines the development of collective bargaining and labor relations through the Wagner Era, and then strikes a balance between historical perspectives of the law and its current problems. The student will be able to identify and trace major trends in the law of collective bargaining, the reason for these trends, and their consequences on the overall functioning of industrial relations.

Stressing the institutional framework in which collective bargaining is cast, the authors probe for the root problems inherent in government efforts to define the rights, duties, and obligations of unions and employers.

With focus on the ever changing and developing laws of labor relations — the **NEW 2ND EDITION of LABOR RELATIONS LAW** integrates into its material:

- Doctrines established by the National Labor Relations Board and the courts, with particular attention to recent NLRB applications of the Taft-Hartley Act and recent changes in the Board's jurisdiction.
- Minority group problems under Taft-Hartley and civil rights legislation.
- The "make whole" doctrine originally established in Ex-Cell-O.

LAW, 2ND EDITION, 1975

- Industrial conflict innovations.
- Developments in the public sector.
- Developments in the control of internal union affairs established by the Landum-Griffin Act.
- The *Collyer* doctrine.

RETAINED FROM THE PREVIOUS SUCCESSFUL EDITION:

- Economic analyses of problems resulting from government influence.
- Analyzes and discusses in an understandable way the major NLRB and court cases, with clear delineation of the cases' significance to employers, unions, employees, and the public.
- Offers an extensive bibliography and a full text of relevant statutes included in the appendices.
- Uses a readable style and careful organization.

1975, 745 pp., cloth (51963-7) $16.50

THE AUTHORS: BENJAMIN J. TAYLOR, University of Oklahoma and
FRED WITNEY, Indiana University.

FROM INDUSTRIAL RELATIONS SECTION, PRINCETON UNIVERSITY

PUBLIC ASSISTANCE FOR MOTHERS IN AN URBAN LABOR MARKET
by Daniel H. Saks, Michigan State University.
Testing the proposition that the welfare system has become a subsector of the economy to which potential recipients respond rationally, Professor Saks examines the trade-off between benefit levels, welfare tax rates, and labor-market opportunities. He recommends a middle ground between case-by-case discretion and a uniform negative income tax in which programs are tailored to the needs of each segment of the welfare population.
1975. 103 pp. $3.50.

PUBLIC ASSISTANCE AND WORK EFFORT: THE LABOR SUPPLY OF LOW-INCOME FEMALE HEADS OF HOUSEHOLD
by Robert G. Williams, Mathematica.
This study provides strong evidence of a causal relationship between elements of the AFDC program and the work effort of its recipients. It presents estimates of the effect on budgetary costs and labor supply of altering implicit tax rates on earnings, rates that are shown to have been considerably lower than those specified in the statutes. 1975. 128 pp. $3.50.

FORTHCOMING SPRING 1976

EVALUATING THE LABOR MARKET EFFECTS OF SOCIAL PROGRAMS. Contributions by Orley Ashenfelter, James Heckman, George Johnson, Dale Mortenson, Finis Welch, Morris Goldstein and Robert Smith. Estimated 250 pp. Approximately $5.00.

Industrial Relations Section, Princeton University

PROGRESS AGAINST POVERTY

A Review of the 1964-1974 Decade

by ROBERT D. PLOTNICK and
FELICITY SKIDMORE

A Volume in the
INSTITUTE FOR RESEARCH ON POVERTY
POVERTY POLICY ANALYSIS Series

In 1964, the war on poverty was declared. Now, more than a decade later, it is appropriate to reflect on what has been accomplished in the war against poverty during the period from 1964 to 1974. PROGRESS AGAINST POVERTY provides a comprehensive, detailed, analytical report of changes in the United States poverty population in the 1964-1974 decade. Using both absolute and relative definitions of poverty, it studies in detail the major trends in the size and demographic characteristics of the poverty population, assesses the impact of macroeconomic conditions on the extent of poverty, and analyzes the contribution of the cash transfer system toward reducing poverty.

1975, 254 pp. cloth, $12.50/£6.50;
paper, $4.50/£2.35

THE PATTERNS OF INTERRACIAL POLITICS

Conflict and Cooperation in the City

by PETER K. EISINGER

A Volume in the
INSTITUTE FOR RESEARCH ON POVERTY
MONOGRAPH Series

This book is one of the few to attempt to make explicit the implications for elite behavior of the configurations of attitudes and behaviors of ordinary citizens. Based on survey data collected in Milwaukee in 1970, it details the patterns of political behavior and belief among blacks and whites in Milwaukee, and shows how these patterns help structure the context of costs and opportunities that bear on elites as they forge relations of conflict or cooperation between majority and minority groups. It deals with elites and masses, political integration and goals, and patterns of conventional political participation, and also presents survey data on issues, such as protest and community control, not normally covered in conventional surveys.

1975, about 220 pp., $11.00/£5.70

ENTRY INTO THE AMERICAN LABOR FORCE

by MICHAEL D. ORNSTEIN

A Volume in the
QUANTITATIVE STUDIES IN SOCIAL
RELATIONS Series

ENTRY INTO THE AMERICAN LABOR FORCE analyzes the critical first years of men's work experiences. It focuses on the effects of race, family background, and education on the levels of first jobs, and, secondly, on the educational, occupational, and wage mobility which takes place during their first years in the labor force. The book is based on retrospective life histories from a national sample survey of about 1600 men between the ages of 30 and 39. In order to facilitate comparisons between whites and blacks, blacks were oversampled so they constitute almost one-half of the respondents. These interviews, which recorded the characteristics of every job held from the age of fourteen, make possible a highly detailed longitudinal analysis of job mobility.

1975, in preparation, abt. $12.00/£6.25.

SCHOOLING AND ACHIEVEMENT IN AMERICAN SOCIETY

edited by WILLIAM H. SEWELL, ROBERT M.
HAUSER, and DAVID L. FEATHERMAN

A Volume in the
STUDIES IN POPULATION Series

This outstanding collection of fifteen papers focuses on a subject of timely and pressing interest—the complex effects of schooling on socioeconomic achievement in American society. The papers offered here were originally presented at an interdisciplinary seminar on achievement processes sponsored by the American College Testing Research Institute. The book presents a wealth of recent substantive findings, and, though its primary focus is on substantive issues, nearly every chapter contains extensive methodological discussions embodying a wealth of information on the application of modern multivariate statistical techniques, with several chapters modifying on or extending existing statistical methods.

1976, in preparation, abt. $22.50/£11.70

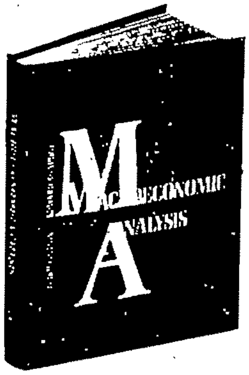
A balanced treatment of theory, measurement, and policy



MACROECONOMIC ANALYSIS

THIRD EDITION

EDWARD SHAPIRO, *University of Toledo*

The third edition of this outstanding textbook continues to provide the intermediate-level student with balanced coverage of the three major aspects of macroeconomics: theory, measurement, and policy. Professor Shapiro covers all the fundamental topics of macroeconomics, developing them at sufficient length to make them comprehensible to the average student and relying on carefully written prose and clear, explicit diagrams as his main tools of explanation. This Third Edition incorporates important new material and reflects recent developments in the field of macroeconomics. It includes a new examination of the shortcomings of the Gross National Product as a measure of national welfare; an expanded treatment of the Phillips curve in the chapter on "The Theory of Inflation"; expansion and reorganization of the material on monetary policy and fiscal policy into separate chapters; an analysis and comparison of the monetarist and Keynesian schools of thought; and a new discussion of the relation between economic growth and environmental quality.

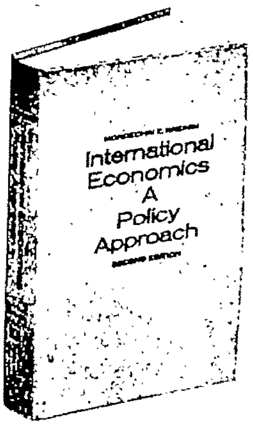
A new edition reflecting new economic realities



INTERNATIONAL ECONOMICS

A Policy Approach

SECOND EDITION

MORDECHAI E. KREININ,
Michigan State University

The new second edition of this highly respected textbook continues to provide a comprehensive, truly international introduction to world finance and trade—one that emphasizes policy and the analysis of general principles throughout. Professor Kreinin thoroughly covers present currency arrangements, analyzes the balance-of-payments problem, offers suggestions for reforms of the monetary system, explains the principles governing world trade, discusses the role of trade organizations, and analyzes selected trade problems among developing nations. This edition has been thoroughly revised throughout to reflect recent developments in international economics: new to this edition are a chapter on international financial developments in the 1970s (including the current oil crisis); a chapter on the trade problems of developing nations (including the 1974 GSP of the European Communities and the proposed GSP of the United States); and sections on the new international currency system and Eurodollars, trade relations of the expanded European community, taxation and the multinational corporation, and the monetary approach to devaluation.

EQUITY IN HEALTH SERVICES
Empirical Analyses in Social Policy

Ronald Andersen, Center for Health Administration Studies, University of Chicago, Joanna Kravits, Massachusetts Hospital Association, and Odin W. Anderson, Center for Health Administration Studies, University of Chicago, Editors

Economic and social issues determining the utilization and distribution of health care services.
288 pp $15.00

ECONOMIC PLANNING, EAST AND WEST

Morris Bornstein, University of Michigan

An authoritative analysis and evaluation of national economic planning in Eastern centrally-administered economies and Western market-oriented economies
416 pp $16.00

INPUT-OUTPUT ANALYSIS IN PUBLIC EDUCATION

Elchanan Cohn, University of South Carolina; and Stephen D. Millman, Maryland State Board for Community Colleges

Techniques for assisting educational managers in the use of input-output analysis for education.
192 pp $14.50

PETROLEUM DISCOVERIES AND GOVERNMENT POLICY
An Econometric Study of Supply

Dennis Epple, Carnegie-Mellon University

Analysis and proposals for changes in government policies affecting production and prices of petroleum to influence new discoveries of crude oil and natural gas. 128 pp $15.00

STUDIES IN NONLINEAR ESTIMATION

Stephen M. Goldfeld and Richard E. Quandt, Princeton University, Editors

New applications of techniques for econometric estimation — switching regressions; production functions; complete systems of demand functions; and models incorporating limited dependent variables.
144 pp $15.00

WHO PAYS FOR CLEAN AIR:
The Cost and Benefit Distribution of Federal Automobile Emission Standards

David Harrison, Jr., Harvard University

Quantitative estimates of the costs and benefits of current federal automobile emission control strategy for various income groups and geographical areas.
192 pp $14.00

For information on these and related Ballinger titles, please write for our catalog.

AGRICULTURAL TRACTORS:
A World Industry Study

Robert T. Kudrle, Center of International Studies, University of Minnesota

A comparative analysis of the structure, conduct and performance of the tractor industry in seven major non-Communist nations. 288 pp $16.50

NON-NUCLEAR FUTURES:
The Case for an Ethical Energy Strategy

Amory B. Lovins and John Price (co-published with Friends of the Earth International)

A closely focused outline of the main technical, ethical, social, economic and policy issues regarding the use of nuclear power.
144 pp (cloth) $11.95 (paper) $5.95

TRANSPORTATION ECONOMICS

Herbert Mohring, University of Minnesota

Suggestions for the application of basic economic theories of price and value to transportation problems. 128 pp $12.50

ADVANCES IN INPUT-OUTPUT ANALYSIS

Karen Polenske, Urban Studies & Planning, Massachusetts Institute of Technology; and Jiri Skolka, Austrian Institute for Economic Research, Vienna, Editors

Proceedings of the Sixth International Conference on Input-Output Techniques, Vienna, 1974.
464 pp $25.00

THE COSTS OF CONGESTION:
An Econometric Analysis of Wilderness Recreation

V. Kerry Smith, State University of New York at Binghamton; and Charles J. Cicchetti University of Wisconsin

Problems of management and resource allocation in low density recreational lands — general methodology for modeling the costs of congestion.
112 pp $12.50

THE DEMAND FOR CHILDREN:
The Economics of Fertility in the United States

Boone A. Turchi, University of North Carolina, Chapel Hill

The first attempt to formulate and statistically test a unified socioeconomic model of fertility in the United States. 256 pp $15.00

HOW TO SAVE GASOLINE:
Public Policy Alternatives for the Automobile

Sorrell Wildhorn, et al., The Rand Corporation

Analytical tools for evaluating public policies for conserving energy used by automobiles — compares various proposals for fuel economy. (A Rand Corporation Research Study) 228 pp $15.00

New Books

Confronting Today's Major Economic Issues

Industrial Market Structure and Performance — 1960-1968

Daryl N. Winn

A rigorous statistical analysis of the relation between market structure and the actual performance of economic units. Prof. Winn focuses on the question: Is the consistent association of above-average returns with industrial market concentration necessarily a result of direct cause and effect (an assumption fundamental to current key recommendations for antitrust policy), or is it the result of multicollinearity among several phenomena? He explores the influences of capital intensity, growth, business risk, and distortions arising from the use of historical costs, in addition to examining the measures of profitability themselves for systematic bias in observed measures. An important contribution to the literature on public policy and antitrust economics.

Michigan Business Studies I, no. 2, new series; xi+ 236 pages; hardcover **$12.00**

The U.S. Medical Care Industry: The Economist's Point of View

Joseph Morreale, *editor*

Six expert economists assess issues such as: the main economic fallacies inherent in present policies on health care delivery in the United States; the impact of Blue Cross on the price of hospital care; the effectiveness of present subsidies of nurse training, and the essential criteria for an acceptable national health insurance plan. Invaluable background to the debate on National Health Insurance. Economists include Paul Feldstein, Harry Schwartz, Gerald Rosenthal, Donald E. Yett, Rueben A. Kessel, and Herbert Klarman.

Michigan Business Papers, no. 60; xvi + 108 pages; paper **$5.50**

Black Economic Development: Analysis and Implications

William L. Cash, Lucy R. Oliver, *editors*

A variety of perspectives from the literature of the seventies on the history and problems of black economic development in the United States as well as on actual and proposed programs for its improvement. Designed to provide the broadest possible spectrum of thinking about minority economics, this anthology juxtaposes divergent viewpoints from social philosophers, academicians, economists, and activists. A valuable textbook which includes discussion questions and suggestions for additional readings.

430 pages **$8.50**

Minorities at the Crossroads

Gerald F. Whittaker, *editor*

Selected lectures from the 1973 and 1974 Annual Symposiums on the State of the Black Economy. The twelve eminent speakers look at a variety of issues affecting the success of future minority economic growth — revenue sharing, the energy crisis, trade unions, education, income maintenance, and international trade.

xiv + 177 pages; paper **$2.50**

The Economic Effects of Multinational Corporations

Werner Sichel, *editor*

Do multinational corporations benefit or deter international economic units? Five prominent economists with divergent viewpoints confront this question. Includes an analysis of the effect of foreign multinationals in the U.S. economy.

FOURTH EDITION

The new Fourth Edition of CONTEMPORARY ECONOMIC PROBLEMS AND ISSUES is a 15-chapter text that discusses just what the title says—current economic issues. This edition contains 2 new chapters on some controversial topics: "THE ENERGY CRISIS—REAL OR CONTRIVED?" and "FOOD—WHAT HAPPENED TO THE SURPLUSES?"

We know your students will find the topics interesting, but since seeing is believing, here is a chance to preview the Table of Contents:

Chapter
1 UNEMPLOYMENT—WHY AND FOR HOW LONG?
2 INFLATION—HOW MUCH AND WHERE DOES IT HURT?
3 WAGE AND PRICE CONTROLS—ARE THEY NECESSARY?
4 POVERTY—HAVE WE CURED IT?
5 INCOME—SHOULD IT BE GUARANTEED?
6 THE NATIONAL DEBT—WILL IT BANKRUPT US?
7 HEALTH INSURANCE—SHOULD UNCLE SAM PAY?
8 FOOD—WHAT HAPPENED TO THE SURPLUSES?
9 CLEAN AIR—ARE WE WILLING TO PAY THE PRICE?
10 URBAN RENEWAL—CAN IT SAVE OUR CITIES?
11 MASS TRANSIT—WILL IT GET US THERE?
12 GOING BROKE—IS REVENUE SHARING THE ANSWER?
13 GOLD—WHO NEEDS IT?
14 THE ENERGY CRISIS—REAL OR CONTRIVED?
15 THE POPULATION EXPLOSION—CAN THE WORLD FEED ITSELF

With topics like this, CONTEMPORARY ECONOMIC PROBLEMS AND ISSUES promises to capture students' interest and be a text they enjoy studying. Examination copies will be available in January. Write for yours today.

SOUTH-WESTERN PUBLISHING CO.

New from

COLUMBIA ESSAYS ON THE GREAT ECONOMISTS

DONALD DEWEY, General Editor

This series is designed to provide concise, authoritative studies of the men who have made the greatest contributions to modern economic thought. The following new titles are now available:

DAVID RICARDO

MICHAEL J. GOOTZEIT

Feeling that research efforts over the past fifty years have sufficiently covered Ricardo's writings on the production and distribution system, Professor Gootzeit, in this new essay, has chosen to emphasize the importance of the monetary system in Ricardo's economic thought.
$7.50, cloth; $1.95, paper

J. M. CLARK

C. ADDISON HICKMAN

John M. Clark's major contributions to modern economic theory—overhead costs, workable competition, and the acceleration principle—are accompanied here by a new look at his work in the field of welfare and his healing advice to economists. $7.50, cloth; $1.95, paper

JOHN MAYNARD KEYNES

HYMAN P. MINSKY

In this radical reevaluation of the work of John Maynard Keynes, an alternative interpretation of Keynes is presented which emphasizes the importance of uncertainty, speculation, and the complex financial structure in generating a "cyclical" rather than "an equilibrium growth" behavior of the economy. $12.00, cloth; $2.95, paper

THE TREATMENT OF MARKET POWER

Antitrust, Regulation, and Public Enterprise

WILLIAM G. SHEPHERD

In this innovative examination of the problems of power and equity in the American economy, Professor Shepherd first presents a new analysis of market power, reassessing its effects and permanence in the modern economy, and then offers suggestions as to how this power should be treated by public policies. $15.00

NEW FROM THE NATIONAL BUREAU OF ECONOMIC RESEARCH

LONG WAVES IN URBAN DEVELOPMENT

MANUEL GOTTLIEB

Using detailed historical records and other available real estate statistics, the author examines long swings in urban development between the early 1840s and the late 1930s. This study brings out the essential characteristics of, and the interplay between, the different elements and processes at work in long swings.

Urban and Regional Studies, 4 $15.00

THE FORMATION AND STOCKS OF TOTAL CAPITAL

JOHN W. KENDRICK

Assisted by YVONNE LETHEM and JENNIFER ROWLEY

In this new book the author builds on his pioneering work in productivity to provide for the first time a comprehensive assembly of estimates of stock of all the types of capital, intangible as well as tangible, resulting from investments.

General Series, 100 $15.00

FOREIGN TRADE REGIMES AND ECONOMIC DEVELOPMENT

JAGDISH N. BHAGWATI and ANNE O. KRUEGER, Editors

This ambitious research project analyzes the phenomena of exchange control, liberalization, and economic development in less-developed countries. The three major topics covered in each country studied are: the anatomy of control, the liberalization episode, and growth relationships.

New Volumes in the series are:

Volume VI: India
by Jagdish N. Bhagwati and T. N. Srinivasin
$15.00, cloth; $5.00, paper

Volume VII: South Korea
by Charles R. Frank, Jr., Kwang Suk Kim, and Larry Westphal $15.00

THE DISADVANTAGED CONSUMER

Alan R. Andreasen, University of Illinois at Urbana

Do the disadvantaged—the poor, the racial minorities, the elderly, the uneducated, the non-English speaking—get their money's worth in the marketplace? Are they victimized by the operating practices of inner city businesses? Have they been helped or hindered by the consumer movement?

This is single best source of information on the special consumer problems of the disadvantaged, providing a systematic, documented analysis of the discrimination they face. Andreasen examines in detail the causes of their disadvantage in the marketplace, and proposes solutions to eliminate or moderate their consumer problems.

355 pages $14.95

MARKETS AND HIERARCHIES: ANALYSIS AND ANTITRUST IMPLICATIONS

A Study in the Economics of Internal Organization

Oliver E. Williamson, University of Pennsylvania

A ground-breaking study of economic organization and antitrust enforcement. Beginning with simple forms of internal firm organization, the author examines increasingly complex forms of economic hierarchies. Antitrust enforcement implications are spelled out with respect to vertical integration, conglomerate organization, organizational innovations, dominant firm industries, and oligopoly. "...a powerful addition to our knowledge ...a stimulus to further research."—Kenneth J. Arrow, Harvard University

288 pages $14.95

THE UNCERTAIN SEARCH FOR ENVIRONMENTAL QUALITY

A Case Study in the Failure of Modern Policy Making

Bruce A. Ackerman and Susan Rose Ackerman, both, Yale University; James W. Sawyer, Jr.; Dale W. Henderson

"...an extraordinary study of the policy-making process. Better than any other analysis that I know of, it deals with the complex interaction among technical, economic, bureaucratic, political, and legal factors that are characteristic of the policy process....A landmark analysis which will be widely used for years to come...."

—Henry S. Rowen, Professor of Public Management, Stanford University

367 pages $13.95

ECONOMIC MAN

The Anthropology of Economics

Harold K. Schneider, Indiana University

Drawing upon the concepts and theories of microeconomics, this book demonstrates their relevance for economic anthropology. It suggests a mode of analysis for understanding not only western and non-western economic systems but also social behavior and activity. "...challenges the bias against the concept of economic man as narrow and greedy."—*Journal of Economic Literature*

Order No. E.75.XVII.4 Cloth $30.00

Summary of the Hearings Before the Group of Eminent Persons to Study the Impact of Multinational Corporations on Development and on International Relations

The hearings which constituted a novel approach for the United Nations, were described by the Group of Eminent Persons in their report as "a most useful source of information, as well as a valuable occasion to test ideas". The present document is published in the light of that opinion, in the belief that it will be of assistance to Governments and to the public in the further elucidation of this complicated issue.

Order No. E.74.II.A.9 $18.00

Industrial Development Survey. Special Issue for the Second General Conference of UNIDO

Order No. E.74.II.B.14 $11.00

REYNOLDS

for timeliness and quality of instruction in the first course in Economics

Available in February

TWO PAPERBACK VOLUMES

MICROECONOMICS: Analysis and Policy
MACROECONOMICS: Analysis and Policy
Revised Editions

by Lloyd G. Reynolds, *Yale University*

The emphasis of the new revised editions is on the *usefulness* of economic reasoning in analyzing policy issues—half of the material deals with "real world" problems.

Readable, teachable, and *learnable,* each volume is short and accurate allowing time for assignment flexibility.

There are no roadblocks, detours, or rough corners in the smooth logical presentations. Each chapter begins with introductory material designed to provide the student with significant guide lines to chapter content. A new "Think about This" section at the end of each chapter poses a relevant Key problem for student discussion.

Each volume has its own separate supporting materials constituting a compact, individual, mini-package. For Micro and Macro each, there is a Study Guide and Workbook by Richard Porter and Dennis Starleaf, an Instructor's Manual and a Test Bank.

Examination copies for adoption consideration available on request; please indicate course title and text presently used.
